Diagnosis and Lithium Treatment of Affective Disorder in the Retarded: Five Case Studies

BY TIMOTHY M. RIVINUS, M.D., AND JEROLD S. HARMATZ

The authors report on five institutionalized retarded patients who had symptoms strongly suggestive of manic-depressive illness and who showed significant symptom reduction in a single-blind placebo-controlled three-year trial of lithium. The number of illness episodes was reduced, and symptoms decreased in all major illness dimensions. These findings indicate that major affective disorder can be both diagnosed and treated in individuals with primary mental retardation.

SYMPTOMS OF manic-depressive disorder in the retarded were observed as early as 1883 (1). Others have continued to note the coexistence of symptoms of major affective disorder and mental retardation (2–10).

Reid (11) found that the incidence of manic-depressive psychosis in a hospitalized population of mentally retarded persons in Scotland was 44 per 1,000 (as compared to an incidence of 33.2 per 1,000 for schizophrenic psychosis). In that study, of the 21 patients with manic-depressive psychosis 11 were depressed, 7 were bipolar, and 3 were manic. The suggested treatment approaches were tricyclic antidepressants, major tranquilizers, and ECT. Naylor and associates (12) used lithium to treat 14 retarded patients in a double-blind crossover study. Six of these patients had bipolar illness, 3 had unipolar mania, 3 had unipolar depression, and 2 were difficult to classify. The number of weeks of illness was significantly reduced on lithium therapy compared to placebo. The number of illness episodes was fewer but not significantly so.

The present study involved prolonged and repeated observations of 5 retarded patients who had symptoms of manic-depressive illness. Diagnosis was established by the most recent criteria (13). Lithium carbonate was compared with placebo over a 3-year period of symptom observation and recording. Factors that might have worked against a successful demonstration of drug efficacy included the difficulty of establishing a diagnosis in the retarded patient and the complexities involved when symptoms are rated and recorded by different personnel, at different times, and over a long period. However, we thought that any drug effect would be apparent if the diagnosis were correct and the treatment specific.

Received Sept. 19, 1977; accepted Jan. 10, 1978.

Dr. Rivinus is Instructor in Psychiatry, Harvard Medical School and Children's Hospital Medical Center, 300 Longwood Ave., Boston, Mass. 02115. Mr. Harmatz is Associate in Psychiatry (Psychology), Harvard Medical School and the Massachusetts Mental Health Center, Boston, Mass.

The authors thank the staff of the state school where this study was conducted for their assistance in recording the data and R. I. Shader, M.D.

METHOD

From a population of 1,300 retarded residents of a state school, one of us (T.M.R.) consulted on 457 residents referred for behavior disorder. Of these, 5 had symptoms suggestive of a major affective disorder of the unipolar or bipolar type (13). A systematic observation and recording of diagnostic symptoms was then begun. Ninety days after symptom observation was initiated, patients were started on a 1-year therapeutic trial of lithium carbonate. At the end of the year, lithium was stopped and placebo substituted during a trial period of at least 90 days. Placebo was stopped and lithium restarted when obvious manic symptoms reappeared. The second lithium treatment period was 1.5 years. Symptoms were systematically observed and recorded throughout the 3 years of the study. The experimental design was known only by one of us (T.M.R.).

Behavioral change was assessed by a list of symptoms or behaviors in five dimensions that correspond to major areas of disturbance as described in proposed *DSM-III* criteria for manic-depressive illness (13). The dimensions associated with mania were increased vocalization, motor activity, aggressiveness and sleeplessness, and decreased appetite lasting over a week. Those associated with depression were mutism, decreased motor activity, withdrawal, sleeplessness or excessive sleep, and decreased appetite lasting over a week (13).

The specific symptom patterns for each patient were selected by a consensus of direct-care staff raters, with the criterion that the symptoms could be reasonably and easily observed and recorded during an 8-hour shift yet still be concordant with the diagnostic criteria for manic-depressive illness. For example, a sign of increased motor activity in 1 patient was translated into an abnormal amount of pacing and flailing of arms on a particular 8-hour shift. The recorders were blind

5	284	42	201	25
Mean	299.0	37.0	278.4	31.0
SD	107.3	24.6	179.3	8.7

[a]Analysis of variance yielded $F(3, 12)=16.8$, $p<.0001$. Hotelling's $T^2=611.5$, $p<.01$. Newman-Keuls comparisons indicated significant differences ($p<.01$) for all combinations of nontreatment (baseline and placebo) versus treatment (lithium and lithium treatment).

to drug changes from lithium to placebo and back to lithium again. For each treatment and placebo period, averages of each patient's symptoms were computed. All symptoms or behaviors were rated equally in the total symptom count.

If, after 90 days of placebo, symptoms had reappeared with increased frequency or severity, clinicians could discontinue placebo. Predrug (baseline), treatment, drug-free, and retreatment periods were compared statistically for the group.

Signed informed consent was obtained for the use of lithium carbonate from parents or legal guardians in all cases and, when possible, from the patients themselves. All medical safeguards recommended for the use of lithium carbonate, including screening for thyroid, cardiac, and renal disease, and regular serum lithium level monitoring, were observed (14). EEGs were done on all patients before and after lithium was started.

RESULTS

All 5 patients had mental retardation (full-scale IQs of 70 or less) of cultural-familial or unknown etiology. Two patients had positive family history for major affective disorder, and 2 had family members whose history was suggestive of major affective disorder. Table 1 summarizes the descriptive data.

There were significant differences in target symptoms between drug-free and lithium-treatment periods (see table 2). Each patient showed a significant decrease in symptoms when lithium was started, returned to a pretreatment level of symptoms when given placebo, and again improved significantly when lithium was reintroduced. The large standard deviations in the untreated periods reflect substantial intersubject differences in the clinical occurrence of symptoms. Standard deviations during treatment periods were small, indicating clinical similarity in regard to observed symptoms among the patients when their conditions improved. Symptoms in all observed dimensions (motor activity, degree of vocalization, degree of irritability, sleep, and appetite) improved to equal degrees in both lithium-treatment periods and relapsed to equal degrees on withdrawal of the drug. No one symptom or subgroup of symptoms appeared to respond better to the drug.

All patients had a significant recurrence of manic symptoms within 5.5 months of the placebo trial but none showed mania or depression during the lithium treatment (1 year) or retreatment (1.5 year) periods. This suggests a substantial reduction in illness episodes.

There were no complications or significant side-effects attributable to lithium therapy. EEGs were normal or nonfocally abnormal before lithium administration. Subsequent EEGs taken in patients 3, 4, and 5 at 1 week, 1 month, and 6 months after the administration of lithium were not significantly altered, and no observable seizures occurred. Two case vignettes are presented below to illustrate features of diagnosis and methods of clinical investigation of the group described.

CLINICAL VIGNETTES

Case 1. Ms. A, a 30-year-old woman, was placed in the state school when she was 11 years old. Her father was unknown, and no family history could be obtained from the paternal side. Her mother was known for promiscuity and antisocial behavior. One of her maternal uncles was an alcoholic and another had spent extended periods in a state mental institution.

Ms. A was the product of a normal gestation, labor, and delivery. Her developmental milestones were slowed, and she became a behavior problem when she started school. She had a short attention span and was disruptive. At the age of 11, when she was admitted to the state school, she had a full-scale IQ of 68 (performance=66, verbal=70).

She was always described as very active and talkative but was able to attend school and obtain employment. However, at age 25, she began to have episodes in which she became so disruptive, confused, and hyperactive that she would lose her job. During these episodes she intruded into the affairs of others and became threatening and assaultive. Seclusion appeared to calm her. A major tranquilizer in a moderate dosage was also helpful. The episodes subsided in 3–4 months and she was then able to return to her job. She had one episode a year from ages 25 to 28.

When she was 28, Ms. A was seen by a psychiatrist, who reviewed her history with the staff. A diagnosis of recurrent mania was considered. She was started on lithium in adequate doses and the major tranquilizer, which she had received for 4 years, was stopped. She had no episodes or outbursts during the year of lithium treatment. Then 16 weeks after placebo was started, she had an episode wherein she again became assaultive, hyperactive, sleepless, and overtalkative. Lithium was restarted and in 14 days she was much improved.

The patient has remained on lithium for an additional year and a half and has had no further manic episodes. She has remained steadily employed and was recently placed in a half-way house.

Case 2. Mr. B, a 28-year-old man, was placed in the state school by his parents when he was 11. His father and two paternal uncles were known to drink and gamble. There was a possibility that his mother had battered several of her children, three of whom (in addition to Mr. B) were said to be retarded. A maternal grandmother was reported to have committed suicide in a state hospital.

Mr. B was the fourth of 8 children. He was the product of a normal gestation, labor, and delivery. He had late developmental milestones and was said to be a withdrawn, fearful child. Social workers involved with the family suspected that he had been abused on a number of occasions, and there was some evidence that he had spent long periods locked in a closet during his early years. At the age of 11 he was placed in a state school for the mentally retarded by court order because he lacked schooling and adequate medical care.

On admission to the state school, Mr. B was fearful and withdrawn and uttered only stereotyped phrases and words. He threatened the examiner who tested him. Results of testing indicated he was severely impaired, with a full-scale IQ of 28. Organic impairment was not evident on psychological tests or neurologic examinations.

He soon became one of the school's severest behavior problems. He usually remained by himself but occasionally assaulted staff members and other residents. When Mr. B was 20, a staff member who had known him for several years observed that he had "good periods," lasting at times for 6 months to a year, during which he was easily manageable and generally withdrawn. However, every 6 months to a year he would, in the argot of the institution, "go on a bat." The staff noticed that he would pace more, sleep only 3–4 hours a night, mutter more, and assault other residents and staff. He also hit walls and attempted to break windows. Various doses of various major tranquilizers did not abort these episodes.

Mr. B had recently broken the rib of a staff member and three of his own fingers. He had also broken bones of his wrist and forearm, which necessitated his admission to a local general hospital. In the hospital, he kicked a wall and broke several bones in his foot and despite a heavy cast, was so agitated and violent that it was thought necessary to restrain all of his limbs. At the suggestion of the psychiatrist, he was started on haloperidol and restricted to a single room. He soon became manageable in the general hospital on this regimen, and after his cast was removed he was discharged.

After an uneventful period of five months during which he was generally withdrawn and not agitated, he began to pace and shout more and assaulted staff members and other residents. Despite increased doses of haloperidol, he smashed a window, severing two tendons at the wrist and breaking several small bones in his fingers. He was rehospitalized. The psychiatrist considered using the lithium protocol for apparent recurrent manic episodes. He was started on lithium, and haloperidol was stopped. His behavior improved, and within 2 weeks he was relatively calm and easily manageable. He was discharged and maintained on lithium for 1 year. During that year, he had no episodes of assault or self-injury. He occasionally threatened staff and other members but did not "escalate" in the way he had before.

After 1 year, lithium was stopped and placebo was started. Four months later Mr. B began to escalate in characteristic ways. Haloperidol was started immediately, but despite this he smashed a wall with his fist and again broke multiple bones in his fingers and wrist. Within 2 weeks of hospitalization on a combination of lithium and haloperidol, he became manageable. Haloperidol was tapered and stopped within a month. He has continued on lithium for a year and a half and has not injured himself or the staff in this time.

DISCUSSION

Institutionalization per se can produce signs and symptoms that resemble major psychosis or major affective disorder. In addition, mental impairment clouds or confuses attempts at secondary psychiatric diagnosis. However, major psychiatric diagnosis can and should be made in some institutionalized mentally retarded individuals because the treatment can be useful and perhaps central to their habilitation.

The diagnosis of mania in the retarded can best be made by comparing the patient's normal behavior to that he or she exhibits during periods of unstable mood. When vocal function is present, even if speech is incomprehensible, pressure of vocalization can be observed. Increased motor activity appears in the manic phase. When compared to a previous baseline, intrusiveness, assaultiveness, destructiveness, and self-abuse also suggest mania. The duration of symptoms helps differentiate mania from panic states. Confusion, cognitive impairment, and hallucinations can occur during mania but are more easily detected in patients with higher IQs (11). Direct-care staff commonly note changes in eating and sleeping patterns, usually decreased appetite and sleep in mania and either increased or decreased appetite and sleep in depression.

Psychomotor retardation is difficult to differentiate from mental retardation per se, organic deterioration, or psychosis not related to affective disorder in the mentally retarded if the patient's normal function is not known. However, if a retarded patient's normal behavior is well-known to the family and staff, the diagnosis of depression can be made without great difficulty. Cyclically depressed mood and confusion were present in all of the depressed patients we studied. Periodic psychomotor slowing, social withdrawal, loss of appetite, and disturbed sleep patterns were other symptoms of depression.

A controlled study by Naylor and associates (12) indicated that lithium was superior to placebo in the treatment of periodic disorders of mood and behavior

in a group of 14 retarded patients. Our study corroborates this finding by documenting amelioration of symptoms by lithium and by demonstrating symptom relapse when lithium was stopped and placebo substituted. Naylor and associates (12) found a suggestive but not significant difference in the number of episodes of mania or depression when patients were given lithium. The fact that we found illness episodes significantly less with lithium treatment may reflect the relatively high number of bipolar (four) and unipolar manic (one) patients and absence of any unipolar depressed patients in our group. The young age of our patients may also have predisposed to a successful result with lithium (15).

The experimental procedure used in this study allowed staff to select symptoms they could easily observe and record that were in accord with major criteria of manic-depressive disorder. Such a flexible recording system is inexpensive and practical given the cooperation of invested direct-care staff, even if they are not trained in research procedures. The large number of different staff recorders (fifty) and recording periods in this study might have obscured a drug effect. The significant and positive drug effect demonstrated is, therefore, all the more compelling and suggestive of the important contribution of lithium carbonate as a treatment for the subjects in the study.

No seizures occurred in the patients, three of whom had nonfocally abnormal EEGs before lithium treatment. These focal abnormalities improved in two patients and were unchanged in the third. Our experience suggests that lithium can be used without the risk of seizure in retarded patients in the same way as it has been used in some epileptics (16–18). Lithium-related status epilepticus, as described by others (19, 20), was not encountered.

The results suggest that among an institutionalized mentally retarded population, unipolar and bipolar affective disorder, as first outlined by Kraepelin (3) and refined by recent diagnostic criteria (13), can be diagnosed and effectively treated with lithium carbonate. We feel that the correct criteria for diagnosis of major affective illness should not exclude those individuals with primary mental retardation, and we would not agree with those who feel that manic-depressive illness cannot be diagnosed or does not exist in those with mental retardation (21–23). The presence of manic-depressive disorder as a potentially treatable condition deserves wider attention in texts and reviews of the emotional disorders of the retarded, where it is currently largely unmentioned.

Although they require further replication, our results suggest the importance of the evolving medical model (24) as it relates to major affective disorder. Symptoms that might otherwise have been considered random or peculiar to a particular individual were identified by using diagnostic criteria and the help of families and direct-care staff as corresponding to a specific and well-described illness for which there is a specific treatment. Once an adequate rating system for these symptoms is devised, an additional effective treatment modality could be documented and proved to be an important contribution to the multidisciplinary efforts to habilitate these patients.

The Efficacy of Drugs and Psychotherapy in the Treatment of Acute Depressive Episodes

BY MYRNA M. WEISSMAN, PH.D., BRIGITTE A. PRUSOFF, PH.D., ALBERTO DIMASCIO, PH.D., CARLOS NEU, M.D., MAHESH GOKLANEY, M.D., AND GERALD L. KLERMAN, M.D.

The efficacy of tricyclic antidepressants and various psychotherapies, in comparison with one another or in combination, has not been fully established in randomized clinical trials. The authors present a randomized controlled trial comparing the combination of amitriptyline and short-term interpersonal psychotherapy, either treatment alone, and nonscheduled supportive psychotherapy in ambulatory patients with acute depression. They found that pharmacotherapy and psychotherapy alone were equally efficacious and better than nonscheduled treatment. The combination treatment of psychotherapy and pharmacotherapy was more effective than either treatment alone and delayed the onset of symptomatic failure.

IN CLINICAL PRACTICE the major treatments for acute depression are tricyclic antidepressants and various psychotherapies. Their efficacy, either in comparison with one another or in combination, has not been fully established in randomized clinical trials.

Ideally, before proceeding to studies including both drugs and psychotherapy, there should be evidence for the efficacy of each treatment alone, in comparison with one another, and, finally, in combination (1). For depression, such information is only partially available. There are many studies showing the efficacy of pharmacotherapy alone (2). We are aware of no published studies of psychotherapy alone in a homogeneous sample of more than 10 acutely depressive patients (3–6), although several are now under way (7–9). The one comparison study of imipramine versus cognitive therapy in acute depression (10) showed a positive effect for cognitive therapy over imipramine. There have been three studies comparing maintenance tricyclic antidepressants and various psychotherapies in recovering depressed patients (11–14). In general, these studies support the value of combining drugs and psychotherapy.

This paper will report on a 16-week controlled clinical trial conducted collaboratively by two clinics comparing the efficacy of tricyclic antidepressants and short-term interpersonal psychotherapy each alone and in combination in acutely depressed patients. Other publications will describe the study in detail (15).

METHOD

Patients

Acutely depressed male and female ambulatory patients aged 18–65 were considered eligible for inclusion in the study. Inclusion criteria also required a nonbipolar, nonpsychotic, acute primary major depression of sufficient intensity to reach a score of at least 7 on the Raskin Three Area Depression Scale (range, 3–15) (16). The diagnosis of major depression was made by a psychiatrist using the Schedule for Affective Disorders and Schizophrenia interview (17) and based on the Research Diagnostic Criteria (18).

Excluded were patients with another predominant disorder, such as organic brain syndrome, schizophrenia, or mania. Patients were also excluded who failed to respond to a previous course of weekly psychotherapy of at least 3 months' duration, who were currently in psychotherapy, who had had an adequate trial of amitriptyline in the past 3 months, or who had a history of medical disorder precluding the use of tricyclic antidepressants.

Design

Patients who met the initial inclusion criteria were assessed over 1 week to exclude patients who remitted

0002-953X/79/05/0555/04/$00.45 © 1979 American Psychiatric Association

rapidly without specific treatment. Rapid remission was defined as symptomatic improvement sufficient to rate a 6 or less on the Raskin scale during the no-treatment evaluation week. After the evaluation week eligible patients were randomized into one of four treatment cells, as follows:

Psychotherapy alone consisted of at least one weekly 50-minute session with the treating psychiatrist. No psychotropic drugs were allowed. The nature of the psychotherapy, as described in an unpublished manual of the Boston-New Haven Collaborative Study, was short-term, interpersonal, and focused on the social context of the depression.

Pharmacotherapy consisted of amitriptyline in a flexible divided dose, 100–200 mg, which was raised to 125 mg within a week, stabilized over the next 3 weeks, and maintained for the next 12 weeks.

Psychotherapy plus pharmacotherapy consisted of both treatments as described above.

Nonscheduled treatment involved assigning patients a psychiatrist whom they were told to contact whenever they felt a need for treatment. No active treatment was scheduled, but the patient could telephone and, if his or her needs were of sufficient intensity, a 50-minute session (a maximum of one a month) was scheduled. This procedure allowed a patient to receive periodic supportive psychotherapy "on demand."

Independent Clinical Evaluation

Participation in the study was only by the informed consent of the patients. Procedures were explained verbally and in writing before patients entered the study. All of the patients were seen for clinical assessment after 1, 4, 8, 12, and 16 weeks, or at the termination of treatment, by a clinical evaluator (a psychiatrist or a psychologist) who was independent of and blind to the patient's treatment. Patients were instructed not to discuss with the evaluator the type of treatment they were receiving. The treating psychiatrist also evaluated the patient. Based on a weighted Kappa analysis, agreement between clinical evaluator and psychiatrist, using the Raskin Three Area Depression Scale (16), was excellent and significant ($p<.001$) in both clinics.

Symptom Failure As an Outcome Criterion

Multiple outcome measures were used (15). The main outcome criterion for this presentation was symptomatic failure, defined as a Raskin depression score of 9 or more, as rated by the clinical evaluator after 8 weeks of randomized treatment. Patients who had previously responded and then worsened as well as patients who had never shown substantial clinical improvement were considered symptomatic failures, as were those in whom the clinical evaluator or the treating psychiatrist noted risk of suicide or rapid worsening of symptoms requiring alternate active intervention, hospitalization, or ECT at any time during the study. All symptomatic failures were withdrawn from the study and treated as clinically indicated.

Other Criteria for Withdrawal

Patients who made substantial deviations from the randomized treatment condition (e.g., refusal of medication or failure to attend psychotherapy) were withdrawn at the point of deviation. However, if the symptoms of these patients did not get worse they were not considered symptomatic failures.

Statistical Analysis

A life table approach (19, 20) was used to calculate symptomatic failure rates. Patients withdrawn from the study for reasons other than symptomatic failure, such as noncooperation, were treated in the analysis as censored observations, i.e., as if they were lost to follow-up at the time of their withdrawal.

RESULTS

Characteristics of the Patients

Ninety-seven patients entered the study. One of these was a "rapid remitter." Therefore, 96 patients were randomized into treatment (51 in Boston, 45 in New Haven). However, 15 of the randomized 96 patients refused the treatment assigned and did not complete 1 week of treatment. They have been excluded from the efficacy analysis, leaving 81 patients for analysis. There was no difference in sociodemographic or clinical characteristics between patients who completed 1 week of treatment and those who did not or between treatment groups.

Reasons for Termination

Table 1 shows the completion rates and the reasons for early termination. Sixty-seven percent of the patients in combined treatment completed the full 16 weeks, compared with 48% in psychotherapy alone, 33% in pharmacotherapy alone, and 30% in the nonscheduled group.

Relative Probability of Symptomatic Failure

Figure 1 presents the probability of symptomatic failure over the 16 weeks in the various treatment groups. The lowest rate of failure was in the combination treatment group and the highest was in the nonscheduled treatment group.

Table 2 shows the significance of the difference in the survival curves presented in figure 1. Patients in the three active treatment groups showed a significantly lower failure rate than those in the nonscheduled treatment group. Although there were fewer relapses in the combined treatment group than in either psychotherapy or pharmacotherapy alone, this difference was significant at only the $p<.10$ level. There were no statistically significant differences in failure rates between the two single treatments of psychotherapy and pharmacotherapy.

In the nonscheduled group there was a steady increase in failure that began early in the first week and

TABLE 1
Reasons for Termination from Randomized Treatment, by Treatment Groups

[a]According to the Gehan modification of the Wilcoxon test (20).

increased until week 12, when it reached a plateau. There were no symptomatic failures in the combination group before week 12. The independent clinical evaluator, who was blind to the treatment conditions, was required by the protocol to withdraw at 8 weeks patients who were symptomatic at the Raskin level of 9 or higher. No patients in the combined treatment group were withdrawn at this point. In the pharmacotherapy alone and psychotherapy alone groups there were no failures before week 8.

DISCUSSION

These data suggest that the combination of tricyclic antidepressants and short-term individual psychotherapy is more efficacious than either treatment alone or than nonscheduled treatment for acute depressive episodes. Either treatment alone, whether drug or psychotherapy, was about equal and more efficacious than nonscheduled treatment. Moreover, the combination treatment delayed the onset of symptomatic failure if it did occur.

Research on the psychotherapy of depressive disorders has been developing rapidly, and a number of studies are currently in process. Although we are aware of no directly comparable studies completed as yet, the study of Rush and associates (10) is similar. These authors compared cognitive therapy with imipramine and found cognitive therapy to be more efficacious in reducing symptoms and preventing attrition. We did not find that psychotherapy was more efficacious than pharmacotherapy. The individual treatments were equally efficacious and better than nonscheduled treatment. The study of Rush and associates did not have a combined treatment group or a control group, so we do not know if they would have found the combination treatment superior or if their active treatments were superior to a control treatment.

Our results also showed that most of the depressive patients did not recover spontaneously in the short run. Although there was mild symptomatic reduction during the evaluation week, the patients were still symptomatic and still required treatment. Only 1 patient out of 97 was considered a rapid remitter without specific treatment. Before concluding that rapid remission did not occur, we must acknowledge possible selection due to help-seeking and referral patterns.

The nonscheduled treatment group, which was not offered regularly scheduled treatment, had the worse overall outcome. Despite their generally poorer outcome, a small proportion of patients in this group were not symptomatic failures and reported satisfaction with this treatment. Our own clinical experience with depressed outpatients has been that some of them report comfort in knowing help is available but prefer to contact the therapist as they feel it is indicated rather than on a prescribed basis. It should be emphasized that this group was not a no-treatment or a no-contact group. These patients had the security of knowing that they could contact the clinic, and they knew they were to be seen for regular research assessments. Although the majority of the patients required more active intervention, it would be important to be able to predict who are the substantial minority of patients who responded to this infrequent, nonscheduled treatment.

There were major differences in the patients' acceptance of different treatments. Thirty-two percent of the patients assigned randomly to psychotherapy dropped out before the first week. Initial nonacceptance of treatment was lower in the groups offered pharmacotherapy: only 17% dropped out before the first week. However, during the course of treatment, 25% of the patients in the pharmacotherapy group discontinued their medication. Since the efficacy of drugs alone and psychotherapy alone was about equal and both treatments were better than nonscheduled treatment, the patient who does not accept psychotherapy may be a good candidate for drugs alone, and vice versa.

We should comment on the generalizability of these data. Our sample of patients were all ambulatory and had a diagnosis of neurotic depression according to *DSM-II* and major depression according to *DSM-III*. There is controversy as to whether they would be considered unipolar because of the differing requirements of number of previous episodes. They definitely were not bipolar or psychotic depressive patients.

CONCLUSIONS

Combined tricyclic antidepressant treatment and weekly short-term interpersonal psychotherapy reduces overall symptoms in ambulatory patients suffering from a nonpsychotic, nonbipolar major depression better than either treatment alone or nonscheduled and irregular contacts with a psychiatrist. For the patient who will not accept the combination of treatments, either pharmacotherapy or psychotherapy alone is preferable to nonscheduled contact. Future publications will describe in detail the rationale for our study design, particularly the exclusion of a placebo group, the specifics of the psychotherapy, and the differential outcomes of drugs and psychotherapy on clinical symptoms (15).

Depression Treated with Imipramine and ECT: The DeCarolis Study Reconsidered

BY DAVID AVERY, M.D., AND ALDO LUBRANO, M.D.

The authors reevaluate a large prospective Italian study (437 patients) that compared high-dose imipramine with ECT treatment in the treatment of depression. The superiority of ECT was evident among patients with endogenous depression, and especially evident among those with delusional depression (83% improved with ECT versus 40% with imipramine) and depressions defined as severe (83% versus 35%).

IN 1964 in the Italian journal *Sistema Nervosa*, DeCarolis and associates published one of the largest studies (437 patients) comparing ECT and imipramine in the treatment of depression (1). This study is one of the few to compare ECT with high-dose imipramine therapy—at least 200 mg/day to a maximum of 350 mg/day for 25 days. The study is unique in that all 437 patients were given the trial of imipramine, and the ECT group was composed only of the imipramine failures. Unfortunately, the English readers' only exposure to the article has been a short *Excerpta Medica* summary in which the authors presented their data in such a way that the efficacy of imipramine was emphasized (2). A look at the original data is crucial to an adequate understanding of the study.

METHOD

The study included 183 men and 254 women who were hospitalized for depression at the University of Genoa Hospital. The mean age was 47.3 years. The depressions were classified into eight types: 1) manic-depressive psychosis—bipolar affective disorder, depressed phase; 2) endogenous monopolar depressive psychosis—unipolar depression, without manic episodes, with clear periodicity (these were "frankly endogenous"); 3) cycloid psychosis—as described by Kleist (3) and Leonard (4), psychosis associated with a clearly phasic course but atypical, i.e., schizophrenic symptoms such as catatonia, delusions, and feelings of influence; 4) atypical depressive psychosis—psychosis associated with a strong delusional component, dissociative symptoms, a clinical picture dominated by depressive symptoms, and no evidence of periodicity; 5) symptomatic depression—secondary depression, e.g., depressive symptoms secondary to schizophrenia; 6) psychoorganic depression—depression associated with deterioration or organic lesions clearly evident clinically or radiographically; 7) neurotic depression—depression associated with a structural conflict and clearly abnormal personality traits, e.g., phobic-obsessive; 8) reactive depression—depression with a very clear relationship between the precipitating event and the psychopathology; patients who had had a previous episode of an endogenous type were not considered in this group.

The depressed patients were also examined for the presence of specific symptoms, presence of precipitating events, and severity (mild, moderate, or severe). A severe depression was defined by the presence of suicidal ideation and alteration of psychomotor activity, either retardation or agitation.

All 437 patients were started on imipramine at a minimum dose of 200 mg/day to a maximum of 350 mg/day for at least 25 days. In some cases the imipramine had to be given parenterally. In some cases a barbiturate or phenothiazine was added. All patients whose trial of imipramine was unsuccessful after a period of 30 days were started on a course of ECT (a minimum of 8 treatments, a maximum of 10).

Evaluation by at least two of the authors took place at least one month after the end of treatment. A patient was considered improved if he recovered with rebound euphoria; returned to his premorbid personality, *resitutio ad integrum*; or showed remarkable improvement and was essentially reintegrated socially. A patient was considered unimproved if there was worsening of symptoms; no change in symptoms; or improvement was insufficient for return to social functioning.

DeCarolis used 437 as the denominator to express the percentage of patients who improved with ECT, even though the total number of those who received ECT was 437 minus the number who responded to imipramine. Even when a subgroup of the total sample

(e.g., delusional depression) was statistically analyzed, the percentage who improved with ECT was calculated using the total number of delusional patients as the denominator, whether or not they received a course of ECT.

We recalculated these data simply by dividing the number improved with ECT by the total number who received ECT. Statistical analysis was done using chi-square analysis, two-tailed without Yates' correction. In addition, 196 subjects were followed up for an average of 18 months (range, 8 months to 4 years) for recurrence of symptoms (5, 6).

RESULTS

The results of the recalculation of the DeCarolis data are summarized in tables 1–3. Table 1 shows the percentage response for the diagnostic groups. The clear superiority of ECT is seen among the manic-depressive psychoses, the endogenous monopolar depressions, and the atypical psychoses. Among the neurotic and reactive depressions, a greater percentage responded to imipramine initially compared with the percentage of imipramine failures who responded to ECT.

Table 2 summarizes the percentage response of the different subgroups to the two treatments. The endogenous groups include the manic-depressive psychosis, endogenous monopolar depressions, and the cycloid psychosis. Of the delusional patients 97 had typical depressive delusions (delusions of guilt, self-accusation, low self-esteem, and ruin), and 84 had atypical depressive delusions (hypochondriacal, persecutory, etc.). The superiority of ECT was essentially the same for both types of delusional patients. Table 3 shows that in

the DeCarolis study delusional patients were significantly less likely to respond to imipramine than were nondelusional patients (40% versus 68%, $p<.001$).

In the follow-up study, persisting recovery after imipramine therapy (37%) was found no more frequently than after ECT (38%). However, the duration of the remission with ECT was significantly longer than with imipramine (14 months versus 10 months, $p<.01$).

COMMENTS

There is increasing evidence that the dosage of antidepressant medication may be a crucial factor in antidepressant response. For example, Simpson (7) found that depressed patients receiving imipramine, 300 mg/day, did significantly better than those on a 150-mg dose. In the psychiatric literature written in English, seven studies involving over 2,000 patients conclude that ECT is superior to antidepressant medication (8-14). Three studies involving 200 patients show no difference (15-17). None show antidepressants superior to ECT. In general, these studies used doses of 150-200 mg/day with two exceptions. Kristensen (15) rapidly increased imipramine to 300 mg/day by the sixth treatment day and found a 57% recovery rate (evaluated prospectively), which was comparable to the recovery rate (evaluated retrospectively) seen in the ECT group. Wilson and associates (18) found that imipramine at a 150-mg dose was inferior to ECT, but when 240 mg/day was given to 9 patients, there was no significant difference compared with 10 patients receiving ECT. Because of the question of whether high-dose tricyclics can approach the efficacy of ECT, the large DeCarolis study and its use of imipramine, 200-350 mg/day for 25 days, takes on special significance.

Even though the study is not without obvious flaws in design, it adds much valuable data relevant to common clinical decisions. The study was not blind. The samples of the treatment groups were not independent—the ECT group consisted only of imipramine failures. Yet it would seem that this inequality would bias the data against ECT, since the imipramine failures contained a greater percentage of severely depressed (58%) and delusional depressed patients (57%) than the original sample (39% and 41%, respectively). Furthermore, antidepressant failure in itself may predict a relatively poor outcome (19, 20) and therefore may be a source of bias against a good ECT response. Another weakness of the study is that criteria for depression were not specified; however, it is clear that those with severe depression had suicidal ideation and either psychomotor retardation or agitation. The signs and symptoms of depression of the nonsevere groups were not made explicit.

Despite these methodologic problems, the study is a close approximation to a common clinical practice in the treatment of depression. In many hospitals, the DeCarolis experimental design is the routine way of treating clinical depression regardless of severity. In such a situation there frequently arises an important clinical question that the study addresses: if a depressed patient has not responded to an adequate course of antidepressants, what are his chances of responding to ECT? The data indicate that if an agitated or retarded, suicidal depressed patient has failed to respond to an adequate course of antidepressants, he still has an excellent chance of responding to ECT. The other studies that have shown this to be true used lower doses of antidepressants (9-11).

The neurotic and reactive depressions responded poorly to ECT (see table 1). It could be argued that these patients, being imipramine failures, were the most treatment-resistant and that a greater percentage would have responded had they been given ECT first. Furthermore, because of the lack of criteria for depression in this study, a number of these imipramine failures may not have had signs and symptoms of depression and may have been experiencing chronic characterologic unhappiness, a problem that is unlikely to improve with somatic therapy. Although ECT's efficacy in neurotic-reactive depression relative to imipramine could be questioned, it seems clear that neurotic-reactive depressions respond less well to ECT than do endogenous depressions. This finding is in accord with at least three other investigations (21-23). Although only 2 of 9 reactive depressions responded to ECT the presence of a precipitating event in itself was not associated with a poor ECT response (62% response rate). Thus, a history of a precipitating event in itself should not preclude the possible use of ECT.

The excellent ECT response seen in patients with atypical depressive psychoses suggests that the indications for ECT may not be limited to clear-cut unipolar and bipolar affective disorder. In these patients, although depressive symptomatology dominated the clinical picture, there was no evidence of any episodic nature of the illness, and strong delusional and dissociative symptoms were common.

The data are also relevant to a more common question: what should be the *initial* treatment of a severely depressed person? Although this study cannot offer strict guidelines for this decision, the data can give the clinician a better idea of the probability of response. The DeCarolis data indicate that when the practice of routinely giving a trial of antidepressants first is rigorously followed, the majority of the severely depressed patients will not have an adequate response to the medication (table 2).

A study by McLeod (24) gives indirect support for this finding. The severity of depression has been associated with high plasma cortisol levels and abnormal dexamethasone suppression (25). McLeod found that those depressed patients with a high cortisol level at 8:00 a.m. and those with an abnormal dexamethasone suppression test had a very poor response to antidepressants; only 26% (9 of 35 patients) improved with either imipramine or amitriptyline, 150-225 mg/day,

for a period of at least four weeks. A significantly greater percentage of improvement, 63% (22 of 35 patients), was seen among those depressed persons who had normal cortisol levels and a normal dexamethasone suppression test ($p<.005$) (24). The implications of these data are broadened by the finding that psychiatric patients who commit suicide have significantly higher cortisol levels than those patients who do not ($p<.01$) (26).

The DeCarolis data also show that the majority of the delusional depressed patients will not have an adequate response to antidepressants. Three other prospective studies led to a similar conclusion (7, 11, 27) (see table 3). On the other hand, delusional depressions respond well to ECT (21, 22, 27). The high probability of antidepressant failure and the resultant prolongation of patient discomfort and increased expense should be factors in determining the initial treatment of delusional as well as severe depressions.

At least two investigations have shown a positive relationship between clinical improvement and imipramine plasma levels, but they also reported that the delusional depressed patient has a poor response to imipramine even at high plasma levels (28, 29). Further studies should be done to resolve whether the establishment of therapeutic plasma levels can increase the efficacy of antidepressants to the quality of response seen with ECT.

Lithium Maintenance: Factors Affecting Outcome

BY JAMES H. KOCSIS, M.D., AND PETER E. STOKES, M.D.

The authors reviewed the charts of 61 manic-depressive outpatients maintained on lithium for 6–75 months for relationships between clinical outcome and various demographic, clinical, and pharmacological variables. Good outcome (50% reduction in episode frequency) did not correlate with any demographic or most natural history variables. A history of frequent episodes was correlated with decreased episode frequency but not with a lower percentage of prophylaxis failure during follow-up. A nonsignificant trend toward decreasing episode occurrence with increasing duration of lithium maintenance was present. Depressions occurred considerably more frequently than manic episodes at adequate maintenance plasma lithium levels. More medication noncompliance was found among patients who experienced both manic and depressive relapses.

THE EFFICACY of lithium carbonate for maintenance therapy of bipolar affective disorder has been established in a number of double-blind, controlled studies (1–8). Results from these studies, however, have shown rates of occurrence of affective episodes in bipolar patients on lithium maintenance as high as 50%. Factors cited as relating to unfavorable lithium maintenance outcome include inaccurate diagnosis (8), previous diagnosis of schizophrenia (9), diagnosis of schizo-affective psychosis (10), rapid cycling (1, 2), lack of insight (11), side effects (12), and inadequate dosage (8, 13, 14). Single reports of more favorable outcome with advancing age (11) and family history of bipolar illness (13) have not been confirmed by others (1, 2, 10).

To gather further evidence relating to clinical and pharmacologic factors in lithium maintenance outcome, we reviewed the records of 61 bipolar patients treated on an open basis with lithium carbonate for 6–75 months (mean= 50.6 months). In this report, we will give the results of this chart review.

Received March 17, 1978; revised July 5, 1978; accepted Aug. 11, 1978.

Dr. Kocsis is Assistant Professor of Psychiatry, and Dr. Stokes is Associate Professor of Psychiatry and Medicine, Cornell University Medical College, New York. Address reprint requests to Dr. Kocsis at Payne Whitney Clinic, 525 East 68th St., New York, N.Y. 10021.

This work was supported by Alcohol, Drug Abuse, and Mental Health Administration grant MH-12464 from the National Institute of Mental Health and by the George Baker Trust Fund.

METHOD

Eighty-eight patients with bipolar affective disorder were admitted to our outpatient lithium program during 1970 and 1971. Of these, 24 patients were seen for less than six months, so lithium maintenance outcome could not be evaluated, and 3 patients were later felt not to have bipolar disorders. The remaining 61 patients were maintained on lithium for 6–75 months (mean= 50.6).

Patients were diagnosed as having bipolar affective illness (at least one episode of depression and mania or hypomania requiring treatment within the past two years) by two psychiatrists, including one of us (P.E.S). Criteria for diagnosis included a history of clear-cut episodes of both depression and mania (hypomania) with typical symptoms (15) and the absence of current Schneiderian first-rank symptoms of schizophrenia. Almost without exception these patients fulfilled Research Diagnostic Criteria (16) for bipolar depression with mania or hypomania, primary (N=51) or secondary (N=10) type. (These criteria had not been published at the time of these patients' admission.) Demographic data for these patients are shown in table 1.

Patients were treated with lithium carbonate on an open basis. Plasma lithium levels were obtained monthly on Monday mornings 12–14 hours after the last lithium ingestion. Zero levels indicate medication noncompliance. Clinic visits were scheduled for every one to four months, and patients were seen more often if this was clinically indicated. At each visit a symptom checklist was filled out and a Payne Whitney Clinic Global (PWCG) rating of affective state (18, 19) was made by a physician. An episode was defined as an occurrence of affective symptoms requiring hospitalization or any additional psychopharmacologic intervention including an increase in lithium dose. Appropriate concomitant medications (phenothiazines or antidepressants) were used or lithium dose was increased as clinically indicated. Although patients were urged to take their medication as directed, no attempt was made to strictly monitor compliance, and the usual problems of outpatient psychopharmacologic treatment occurred.

At the time of admission to the clinic, patients were interviewed by at least two psychiatrists and a thorough history was taken with particular attention to the number and type of episodes and hospitalization during the five years before admission. Good outcome was defined as a decrease of at least 50% in the annual

Total	1.01[b]	.48	.005
Hospitalizations	.33	.07	.005

[a]Paired comparison t test, one-tailed.
[b]35 index episodes were eliminated for purpose of statistical comparison.

Rate of episode occurrence during the lithium maintenance follow-up period.

Data were collected by review of charts, PWCG ratings, and records of plasma lithium levels for each subject. Two factors assessed in addition to demographic and natural history variables were social engagement and condition at entry to the lithium clinic. Social engagement (17) is a factor composed of three points—one for marriage, one for employment, and one for assumption of appropriate family responsibility, e.g., support of children. Three is the maximum score. Condition at entry was defined as whether the patient was continuing or beginning lithium treatment at the time of admission and his or her clinical mood state (manic, normothymic, or depressed).

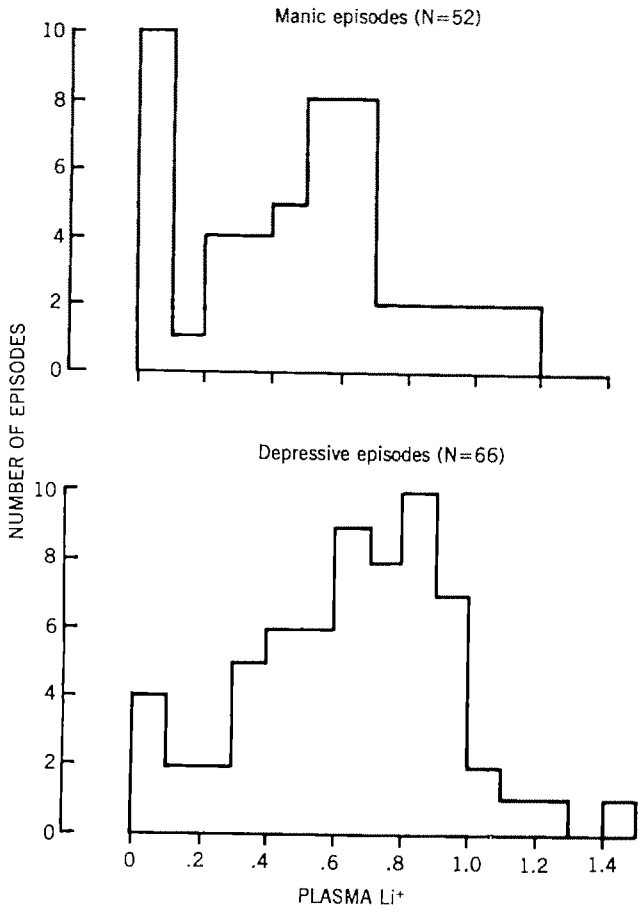
RESULTS

Table 2 shows the annual rate of episode occurrence before lithium clinic admission and during the lithium maintenance period. The frequency of both types of affective episodes and the frequency of hospitalization decreased significantly in the follow-up period.

The relationships between good outcome and demographic and natural history variables are shown in table 1. There was no significant correlation between outcome and most of the variables examined. Patients with a previous history of more frequent episodes had a more favorable outcome. However, because improvement was defined as a percentage reduction in episode frequency this difference may be a statistical artifact.

To determine if this was the case we examined outcome in terms of the percentage of patients who experienced lithium prophylaxis failure, i.e., had at least one affective episode during follow-up, and found that the frequency of previous episodes did not significantly predict differential prophylaxis failure rates in our subjects. However, it was noteworthy that 4 patients with prior histories of frequent episodes (more than 2 per year) had no episodes during follow-ups ranging from 60–75 months.

We found that nine of the ten (90%) secondary bipolar patients had episodes during lithium maintenance, compared to 34 of the 51 (67%) primary bipolar patients. This trend was not statistically significant (the number of secondary patients was small). Preexisting diagnoses in secondary patients included schizophrenia (5), alcoholism (3), and epilepsy (2).



The relationship between episode occurrence and duration of lithium maintenance treatment was examined (in the patients we assigned to lithium at admission). There was a slight trend toward decreasing episode occurrence with longer duration of lithium maintenance treatment, but this did not reach statistical significance. Plasma lithium levels were significantly lower during the three-month periods preceding manic episodes (mean= .47 mEq/liter) than periods preceding depressed episodes (mean= .64 mEq/liter) ($t=2.85$; $p<.01$). Also, more zero levels were recorded prior to manic episodes (10 of 52 episodes) than depressed episodes (3 of 66 episodes), indicating more noncompliance with medication prior to manic episodes. Mean yearly lithium levels taken at anniversary months following admission to the clinic for the patients who experienced no episodes during maintenance treatment was .65 mEq/liter. This was higher than mean levels recorded during the three months prior to manic episodes, depressed episodes, and total episodes (mean= .57 mEq/liter).

The distribution of mean plasma lithium levels before all episodes is shown in figure 1. Seven patients experienced 10 episodes of mania or hypomania at plasma levels consistently higher than .7 mEq/liter. Of these, however, 4 occurred while patients were on concomitant tricyclic antidepressants. Fifteen patients

Plasma Lithium Levels During Three Months Preceding Affective Episodes

Episode Type(s)	Number of Episodes	Plasma Lithium Levels During 3 Months Before Episode		
		Average Mean (mEq/liter)	Number with Mean of 0	Number with Mean >0.7
Manic only (N=13)	28	.52	3	5
Depressed only (N=15)	26	.62	0	10
Manic and depressed (N=15)				
Manic	24	.41	7	5
Depressed	40	.64	3	20
Total (N=43)	118	.57	13	40

FIGURE 1
Distribution of Mean Plasma Lithium Levels (mEq/liter) During the Three Months Preceding Affective Episodes

experienced 30 depressions while plasma lithium levels were consistently higher than .7 mEq/liter. With the exception of three hospitalizations and one suicide, these depressions were managed psychopharmacologically on an outpatient basis.

Further relationships between types of episodes experienced by all patients and plasma lithium levels three months prior to episode occurrence are shown in table 3. Patients who experienced both manic and depressed episodes had lower lithium levels prior to their manic episodes and more noncompliance than did patients who experienced only manic breakthrough.

DISCUSSION

In evaluating the annual rate of occurrence of affective episodes and hospitalizations for patients in our lithium maintenance program, it is important to be aware that the treatment was open medication, compliance was not strictly monitored, and that other factors such as the use of concomitant medications and supportive psychotherapy effects were present. However, the marked reduction in the rate of episode occurrence and hospitalization during follow-up further supports the previously reported efficacy of this treatment (1–8).

Good outcome (a greater than 50% decrease in episode frequency) was not correlated with most demographic or natural history variables. Patients with a prior high frequency of episodes (two or more per year) improved at a higher rate than did those with prior low frequency of episode ($p < .05$). However, when outcome was examined in terms of the incidence of prophylaxis failure, the prior high frequency group did somewhat worse than the prior low frequency group. Nonetheless, it was noteworthy that 4 patients with prior high frequency experienced no episodes during lithium maintenance periods ranging from 60 to 75 months. These findings suggest that at least some patients with histories of frequent episodes can benefit from lithium maintenance, although amelioration rather than prophylaxis may be the outcome. There may be some overlap between our prior high-frequency group and the so-called rapid cyclers described by Dunner and Fieve (1).

The trend toward a higher incidence of prophylaxis failure among bipolar patients with a history of preexisting psychiatric or medical conditions compared to those with primary bipolar disorder supports the validity of the primary-secondary distinction originally proposed by Robins and Guze (20). We agree with other authors (8–10) who have emphasized the importance of accurate diagnosis in predicting lithium maintenance response. More research is needed on the place of lithium ion for the treatment of secondary affective disorders.

We observed a slight decrease in the annual rate of episode occurrence with longer duration of lithium maintenance, particularly for depression. This may have related to our increasing awareness in recent

years of the importance of maintaining higher plasma levels. Our data are consistent with the possibility that lithium helps to stabilize some underlying biochemical or humoral disruption in bipolar disorders.

Manic episodes arising with plasma lithium levels consistently above 0.7 mEq/liter, in the absence of concomitant antidepressant medication, were infrequent (2 of 61 patients). Depressive episodes occurring at usually clinically adequate plasma levels were considerably more frequent. However, the depressive occurrences were more frequent early in maintenance and were generally mild and 28 of 30 such episodes responded to outpatient pharmacologic intervention. The finding of more medication noncompliance and lower mean plasma lithium levels prior to episodes in patients who experienced both rather than only one type of recurrence may reflect a practice of some patients to decrease lithium when depression occurs, thus creating a "vicious cycle" with rebound mania in patients in the former group. Our findings point out the importance of adequate medication compliance and adequate plasma lithium levels.

It is important to the patients who develop affective episodes while on adequate lithium maintenance as well as the rapid cyclers who stay well during prolonged maintenance on lithium. If they represent biologically homogeneous groups of responders and "nonresponders," it would be interesting to characterize them clinically and biologically. We recently reported erythrocyte lithium data on a population of these important subtypes (21).

The Delineation of an MMPI Symptom Pattern Unique to Lithium Responders

BY FRED A. STEINBERG, PH.D.

The author attempted to determine whether the Minnesota Multiphasic Personality Inventory (MMPI) would be sensitive to a symptom pattern unique to lithium-responsive patients regardless of diagnosis. Statistical analyses of the MMPI scores of lithium responders, lithium nonresponders, and a group of patients receiving other psychotropic drugs revealed that the depression, psychasthenia, mania, and social introversion scale scores significantly differentiated the lithium response and lithium nonresponse groups. No strong indications of significant difference were found between the MMPI scale scores of the lithium nonresponse and psychotropic groups. The results suggest that there is a lithium-responsive syndrome that exhibits a distinctive symptom pattern regardless of its varying phenomenological features in different individuals.

WITHIN THE PAST 25 years lithium has been acknowledged to have a pronounced therapeutic effect in the treatment of some manic and manic-depressive disorders. A few studies (1–4) have also indicated that a positive response to lithium was observed in patients diagnosed as having recurrent depression, schizo-affective disorders, or acute schizophrenia. The literature (5–6) suggests that recurrent episodes of hyperactivity, excitement, or agitation are common features of individuals with lithium-responsive disorders. However, the regular recurrence of these symptoms does not necessarily indicate which patients will positively respond to lithium therapy. For this reason, the objectification of a basic symptom pattern that is both common among and unique to lithium-responsive patients could have great clinical importance.

Two studies (7–8) attempted to determine whether the Minnesota Multiphasic Personality Inventory (MMPI) could delineate the characteristics of lithium-responsive patients. However, these studies were inconclusive due to methodological deficiencies. I attempted to determine the value of the MMPI for delineating a symptom pattern unique to lithium responders. The data from my investigation were analyzed with respect to the following two hypotheses:

1. At least two MMPI scales will significantly differentiate those who do and those who do not respond to lithium.
2. No MMPI scale will significantly differentiate between patients who do not respond to lithium and patients who are receiving other psychotropic drugs.

METHOD

I used the treatment records and chart documentations of 30 male and 15 female psychiatric outpatients and short-term inpatients who were between the ages of 19 and 63. All patients previously diagnosed as having organic brain dysfunction were excluded from the study due to the possible confounding effects of such impairment on ratings of improvement.

Treatment records were used to assign patients to a lithium response group, a lithium nonresponse group, and a comparison group receiving psychotropic drugs other than lithium. Each group contained 15 patients. The assignment of patients to the lithium response and lithium nonresponse groups was done retrospectively by inclusion of consecutively admitted relevant cases. Each patient's dated medication history was used to determine response or nonresponse to lithium. Patient records used for the psychotropic drug comparison group were chosen randomly.

The drug treatment mode and dosages for patients in all groups were determined by the treating physician prior to this investigation. Most patients initially selected for lithium treatment had episodically recurring disorders marked by agitation, hyperactivity, or excitement. Lithium was prescribed for patients with these pathological features without regard to formal diagnostic categories (see table 1). Subjects were diagnosed as having an episodically recurring disorder if they had had at least one documented episode during the 18 months prior to their latest admission.

The lithium response group consisted of patients whose psychopathology had been stabilized by treatment with lithium alone for a period of at least 4 weeks. It was essential that none of the patients in the lithium response group showed a need for adjunctive

TABLE 1
Diagnostic Composition of Patient Groups

Diagnosis	Lithium Response Group (N=15)	Lithium Nonresponse Group (N=15)	Psychotropic Group (N=15)
Manic-depressive disorder	10	7	0
Schizophrenia	1	2	5
Unipolar depression	1	2	0
Schizo-affective disorder	1	0	0
Cyclothymic personality	1	0	0
Anxiety reaction	0	0	1
Involutional depression	0	1	0
Depressive reaction	0	2	7
Conversion reaction/ depression	1	1	0
Psychotic depression	0	0	1
Hysterical personality	0	0	1

medications once they were stabilized on lithium. Patients who did need other medications during this time period were placed in the lithium nonresponse group. In some cases it was necessary to administer varying doses of adjunctive medications during the initial phases of drug therapy before lithium produced a therapeutic effect. In such cases, lithium responders were defined as patients whose psychopathology was adequately controlled by lithium alone for a period of 4 months after the withdrawal of adjunctive medications. Patients who warranted a represcription of adjunctive medications during withdrawal from these medications were considered lithium nonresponders.

The third group consisted of patients for whom various psychotropic medications were prescribed. Such medications included phenothiazines, dibenoxepins, butyrophenones, tricyclic antidepressants, and monoamine oxidase inhibitors. Patients in this group had a variety of symptoms other than those used as criteria for prescription of lithium.

All patients had been given the MMPI before any therapeutic drug trials to objectively measure symptoms or symptom patterns characteristic of their pathological states. Any patients whose MMPI profiles had an F scale score greater than 80 were excluded from the study. Essentially, only patients with clinically interpretable MMPI profiles were studied.

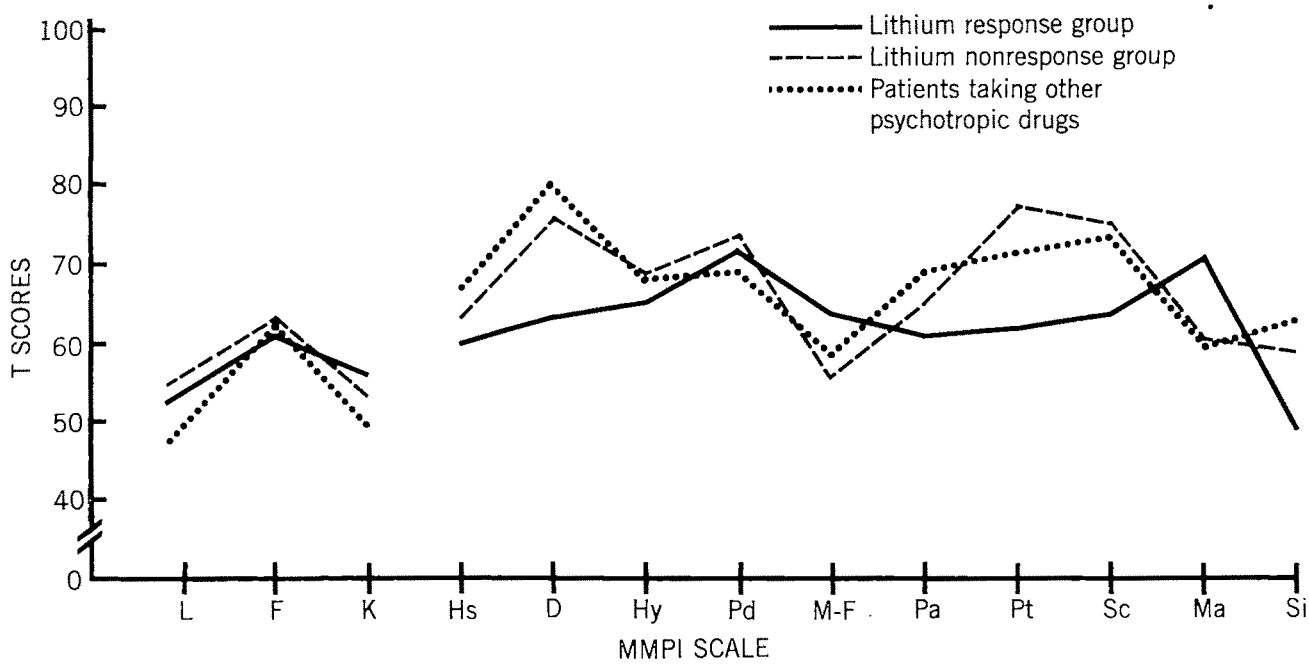
A one-factor between-groups analysis of variance was done for each MMPI scale to determine scales that differed significantly among the three patient groups. These analyses were conducted for the following MMPI scales: L, F, K, Hs, D, Hy, Pd, M-F, Pa, Pt, Sc, Ma, and Si. Post-hoc Newman-Keuls tests were then employed to ascertain which patient group had contributed most to the significant variance of the MMPI scales previously delineated.

RESULTS

Figure 1 illustrates the mean MMPI profile for each group of patients. A one-way analysis of variance was calculated to determine the relative degree to which each scale differentiated between groups. Significant differences among the scores for the three groups were found on the following scales: Ma ($F(2, 42)=4.4243$, $p<.01$); Si ($F(2, 42)=6.742$, $p\leq.01$); D ($F(2, 42)=3.6956$, $p\leq.05$); Pt ($F(2, 42)=3.0583$, $p\leq.05$); and L ($F(2, 42)=3.3280$, $p\leq.05$).

DISCUSSION

The first hypothesis of this investigation was that at least two MMPI scales would differentiate significantly between the lithium response and the lithium nonresponse group. Newman-Keuls post-hoc tests revealed that the Ma scale scores were significantly higher in the lithium response group than the lithium nonresponse group ($W_2=8.77$, $p\leq.05$). Three other MMPI scales were significantly lower for the lithium response group compared to the lithium nonresponse group. These scales include the Si scale ($W_2=8.15$, $p\leq.05$), the D scale ($W_2=13.37$, $p\leq.05$), and the Pt scale ($W_2=14.56$, $p\leq.05$).



The significantly higher Ma scale scores of lithium responders indicate a higher activation level, increased flight of ideas, and emotional excitement when compared to lithium nonresponders (9). Although this finding would be expected, it is interesting that the lithium responders' Ma scale scores are significantly different from those of other patients whose psychopathology also indicated a lithium trial. The lithium response group also had significantly lower D scale scores. This indicates that lithium responders experienced less subjective depression, psychomotor retardation, physical malfunctioning, mental dullness, and brooding (9). The significantly lower Pt scale scores of lithium responders suggest less anxiety, obsessional rumination, and phobic behavior. Finally, the significantly lower Si scale scores of lithium responders show their tendency toward versatility and sociability (9) when compared to the more socially constricted lithium nonresponders.

The second hypothesis stated that there would be no significant differences between the scale scores of the lithium nonresponse group and the group receiving other psychotropic drugs. It was found that the lithium nonresponse group had significantly higher L scale scores than the psychotropic group ($W_3=6.27$, $p\leq.05$). However, since this scale was the only one that suggested a significant difference between these groups and since it also has few items, it is highly possible that this finding was due to chance.

COMMENT

The focus of this study was on the delineation of a symptom pattern unique to lithium responders. Although not conclusive, the results of this investigation

FIGURE 1
Mean MMPI Scale Scores for Lithium Responders, Lithium Nonresponders, and Comparison Group

may be viewed as a description of symptoms that are unique to lithium responders. The predictive capability of these findings remains untested. In addition, because this study included so few female lithium responders and nonresponders, caution should be used when applying these results to female psychiatric patients.

The diagnostic composition of the lithium response group was not as heterogeneous as had been anticipated. Future research in this area should be directed at replicating the results of this study using patient groups that include more diverse diagnostic categories.

Finally, the mean profile of the lithium response group (figure 1) represents an MMPI actuarial code type that is typically termed sociopathic or antisocial personality (10). The results of this investigation suggest that the construct validity inherent in some MMPI actuarial code types may not be keeping pace with our expanding knowledge of various clinical syndromes. Further investigations of the psychological test characteristics of a "lithium responsive syndrome" are encouraged.

Treatment of Tardive Dyskinesia and Mania with RBC Lithium Determinations

BY LARRY ERESHEFSKY, PHARM.D., TERRY N. RUBIN, PHARM.D., AND STEPHEN FRIEDMAN, M.D.

The authors report the usefulness of RBC lithium determinations in managing the treatment of tardive dyskinesia. They present a case report in which manic manifestations and tardive dyskinesia symptoms paralleled the rise and fall of RBC lithium and plasma lithium levels were constant during the period of symptom improvement. They conclude that RBC lithium levels appeared to reflect toxicity, control of mania, and symptom suppression of tardive dyskinesia better than plasma lithium levels alone.

LITHIUM HAS been shown to be useful in the treatment of manic-depressive illness (1–6); several studies on the use of lithium in the treatment of tardive dyskinesia (TD) have demonstrated variable outcomes (7–12). All of these studies used lithium plasma (or serum) levels to monitor therapy; however, recent literature disputes the validity and reliability of following the treatment of affective disorders with Li^+ plasma levels alone (13, 14). Red blood cell (RBC) Li^+ determinations (Hisayasu method) are currently being used as a method of assessing the extent of distribution and uptake into central nervous system tissue (15). This measurement is a more reliable prognosticator of impending toxicity or efficacy (16–22). The development of an organic brain syndrome with ordinarily therapeutic doses of Li^+ has been reported. Plasma levels in the low therapeutic range (Li^+, 0.75 mEq/liter) have been associated with both confusion and hyperactivity. Many reports hypothesize that central nervous tissue concentrations and not plasma levels correlate better with the observed behavioral and neurotoxic effects (23–26). A therapeutic window for the treatment of mania with RBC lithium levels between 0.20 and 0.60 mEq/liter has been proposed (13). Other investigators have found a significantly increased RBC lithium level and RBC/plasma lithium ratio in responders than in nonresponders (14, 16). However, the clinical value of RBC lithium determinations remains a controversy (27, 28). In the case report that follows, RBC Li^+ levels correlated well with suppression of TD, neurotoxicity, and changes in manic symptomatology.

No previous studies have correlated treatment of TD with RBC Li^+ determinations. During the hospital course of our patient, an oculofacial TD characterized by blepharospasms, upward deviation of both eyes, tongue protrusion, and jaw movements was observed.

To more easily interpret the following case report and discussion, a subjective rating scale for mania, organicity, and tardive dyskinesia symptomatology was devised (see figure 1). The staff rated the patient based on severity of the target symptom as outlined in the clinical course. A rating of 1 indicated minimum impairment and a rating of 5 represented maximum severity. Figure 2 illustrates plasma Li^+, RBC Li^+, and the RBC plasma Li^+ ratio versus time during this patient's hospitalization.

CASE REPORT

Ms. A, a 52-year-old black woman with a 25-year history of manic-depressive psychosis was admitted to Los Angeles County/University of Southern California (LAC/USC) Medical Center Psychiatric Hospital. Her medical history included three episodes of Li^+ toxicity, one of which resulted in coma. One week prior to this admission, Ms. A was admitted to another hospital for 5 days because of increasing agitation. Ms. A was discharged from this first hospitalization on 1800 mg/day of lithium carbonate, 1 g of chloral hydrate h.s., and 1 tablet of spironolactone with hydrochlorothiazide (Aldactazide) a day. On admission to LAC/USC Psychiatric Hospital, she exhibited polydypsia, polyuria, abdominal pain, anorexia, drowsiness, ataxia, dysarthria, and confusion. Her pertinent laboratory data taken on admission included plasma Li^+, 2.44 mEq/liter; Na^+, 133 mEq/liter; K^+, 3.5 mEq/liter; and serum creatinine, 1.3 mg/100 ml. Her drug history disclosed the use of moderate to high doses of phenothiazines from 1965 to 1971, including chlorpromazine, trifluoperazine, fluphenazine, and thioridazine together with prophylactic trihexyphenidyl. The daily dose was approximately 600–1000 mg of chlorpromazine or its equivalent. In 1972 thioridazine was discontinued, Li^+ therapy was begun, and Ms. A began to exhibit the TD symptoms. Concomitant neuroleptic therapy for periods of agitation and sleeplessness were employed when necessary.

Received June [illegible]77; revised Sept. 28, 1977; accepted Nov. 7, 1977.

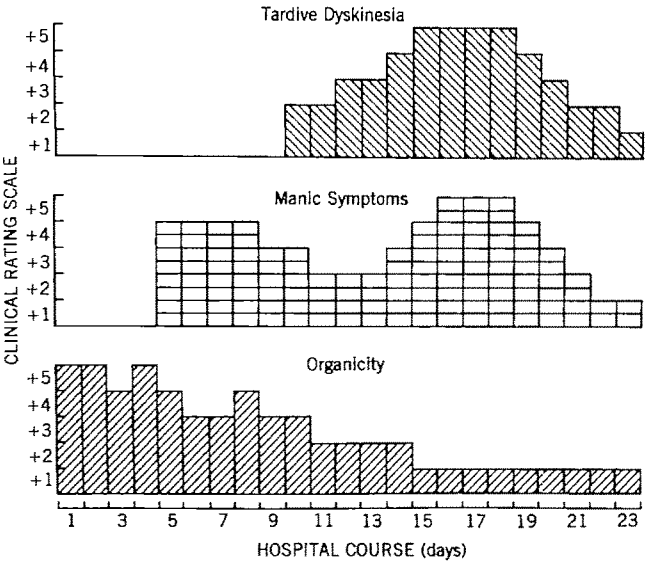

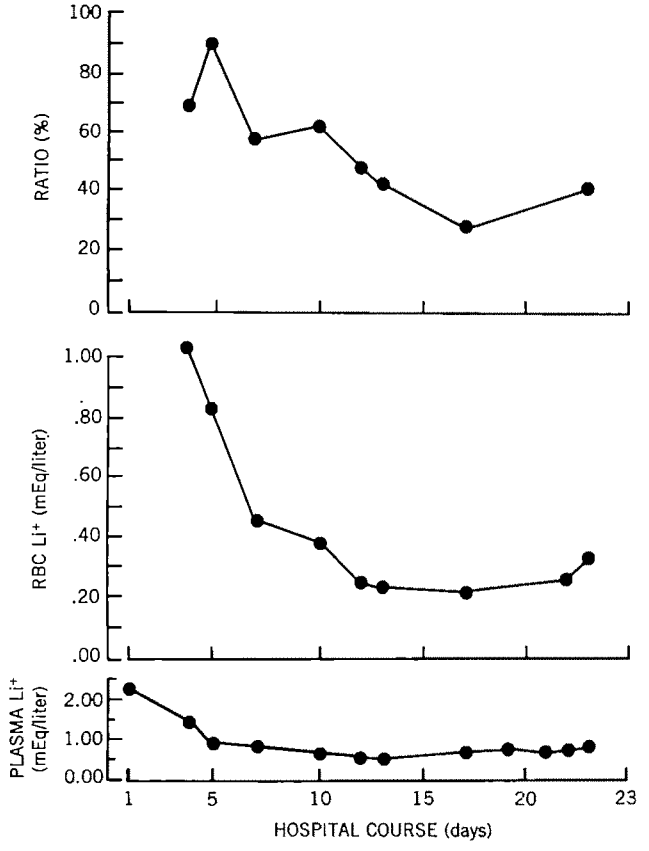

FIGURE 2
Plasma Li^+ Levels, RBC Li^+ Levels, and RBC/Plasma Lithium Ratio

Hospital Course

Days 1-4. On day 1, Ms. A was lithium toxic (plasma Li^+, 2.24 mEq/liter). At this time no medications were administered, but oral fluids (200 ml/hour) were given and no movement disorder was noted. See figure 2 for other lithium values.

Days 5-9. On day 5, Ms. A's lithium carbonate therapy, 300 mg t.i.d., was begun, based on her falling plasma levels and her increasing irritability and euphoria. She was oriented to time, place, and person and was less confused; her speech, although still slurred, was more coherent. During this period her short-term memory slowly improved and the movement disorder remained undetectable. On day 5, her plasma Li^+ was 0.96 mEq/liter, and her RBC Li^+ was 0.84 mEq/liter.

Days 10-13. An improvement in Ms. A's cooperativeness, memory, attention span, and orientation all were noted as evidence of a resolving acute organic brain syndrome. On day 10 writhing movements of the fingers and hands, frequent blinking of both upper eyelids, and masticatory movements of the mouth were independently observed by the nurse, the psychiatrist, and the two pharmacy residents. Daily interviews were conducted by either the psychiatrist or pharmacy residents, and no dyskinesia was observed prior to day 10. On days 12 and 13 finger and jaw movements remained about the same, but upward deviation of both eyes along with increased blepharospasms and involuntary tongue movements were observed. On day 10 her plasma Li^+ was 0.60 mEq/liter, and her RBC Li^+ was 0.37 mEq/liter.

Days 14-15. On day 14, Ms. A became more easily upset, irritable, and loud and displayed a labile affect. Her TD symptomatology worsened; she could not hold out her tongue for more than 10 seconds unless she curled it down resting it on her chin and lip. However, Ms. A remained oriented, had good short-term memory, and displayed minimum residual from her acute organic brain syndrome. The lithium carbonate dose was increased to 1200 mg/day on day 15.

Days 16-20. On days 16 and 17 Ms. A had increasing difficulty falling asleep. Her speech became increasingly pressured as she became agitated. The movement disorder remained about the same as described on days 14 and 15. On day 17 her plasma Li^+ was 0.67 mEq/liter and her RBC Li^+ was 0.21 mEq/liter.

Days 21-23. A noticeable improvement was observed in Ms. A's blepharospasms, and tongue, jaw, and finger movements over this time period. She could hold her tongue out for 25-30 seconds without any apparent discomfort. Her behavior also improved. Ms. A was discharged on day 23 on 600 mg of lithium carbonate b.i.d. On day 23 her plasma Li^+ was 0.75 mEq/liter, and her RBC Li^+ was 0.31 mEq/liter.

DISCUSSION

Lithium's efficacy in the treatment of tardive dyskinesia with the sole use of plasma levels has recently been demonstrated. Reda and associates (9) in a noncontrolled study of six patients demonstrated lithium's usefulness in alleviating but not eradicating symptoms of TD, particularly oral and facial types. Prange and associates (10) demonstrated a dose-related improvement of TD symptoms in two patients who relapsed when placed on placebo. In another study by Reda and associates (8), lithium carbonate in doses of 600-1200 mg/day resulted in a statistically significant improvement ($p<.05$) in bucculolingual masticatory and choreoathetoid movements. Other investigators have

found that dyskinetic movement disorders caused by L-dopa and Huntington's chorea are alleviated by the use of Li^+ (11, 29, 30). Based on the studies by Ashcroft (31), Colburn (32), and Friedman (33), the mechanism of action for Li^+'s beneficial effects are 1) a decrease in the sensitivity of the postsynaptic receptor to dopamine; 2) an increase in the reuptake of dopamine and norepinephrine, and 3) a decrease in dopamine synthesis in the corpus striatum secondary to feedback inhibition. Additional evidence for lithium's antagonistic action on dopamine can be seen in reports of extrapyramidal symptoms induced by lithium therapy (34). These limited clinical trials demonstrated that at least two weeks of treatment was necessary for TD symptom alleviation, even though plasma levels ranged between 0.70 and 1.70 mEq/liter throughout their study period.

Ms. A's toxic picture manifested itself as an organic brain syndrome without any movement disorder. These symptoms as outlined in the clinical course correlated better with the RBC Li^+ levels than with the plasma levels (see figure 1 and figure 2). Lithium plasma levels of 0.53–1.47 mEq/liter were observed from hospital day 4 and thereafter. However, based on criteria published by the University of Southern California pharmacokinetics laboratory (13), Ms. A's RBC Li^+ levels were still considered toxic on day 6 (RBC $Li^+ > 0.60$ mEq/liter) (13). As Ms. A's RBC Li^+ level fell, her organicity improved. It took an additional 5 days for the organicity to abate. Many case reports document this lag period in improvement and explain the phenomenon based on intracellular stores reequilibrating slowly into extracellular fluid (23, 35).

Ms. A exhibited manic symptoms that responded to Li^+ RBC levels within the usual therapeutic range of 0.30–0.40 mEq/liter (16) (figures 1 and 2). Due to the complexity of distinguishing mania from organicity, it was difficult to rate Ms. A or to make generalizations about her early hospital course. Li^+ RBC levels greater than 0.50–0.60 mEq/liter have also been associated with a recrudescence of manic behavior (13, 17). As Ms. A's toxic RBC Li^+ levels decreased, her manic symptoms seemed to decrease. However, as her RBC levels continued to fall, she became increasingly more hyperactive and irritable. Then, as the RBC Li^+ levels increased by day 23, she became more calm and cooperative. It appears that our case has a very narrow "therapeutic window." RBC Li^+ levels greater than 0.24 mEq/liter but less than 0.40 mEq/liter brought her manic behavior under control.

The current literature reports the limited usefulness of lithium in the treatment of neuroleptic-induced permanent dyskinesias. To date no attempt has been made to use RBC Li^+ levels, which correlate better with central nervous tissue lithium levels, as a predictive tool in the treatment of TD. The lag period of 5–10 days that has been cited in the literature as the length of time needed before TD symptom suppression could be observed is the same interval necessary to control manic behavior (7); therefore, RBC Li^+ levels may prove to be a useful tool in the proper assessment of what constitutes an adequate trial of lithium in the treatment of TD as well as mania.

During our contact with Ms. A, TD was first manifested on day 10 of her hospitalization (see figures 1 and 2). Prior to this, her RBC Li^+ levels were appreciably higher and no signs of TD were apparent. In addition, as her RBC Li^+ levels continued to decline the staff noticed marked movement disturbances. These low RBC Li^+ levels coresponded to the period in which the movement disorder was most severe (days 13–21). On day 15, Ms. A's lithium carbonate dose was increased to 1200 mg/day. Her plasma Li^+ levels increased by day 19, but no improvement in TD was observed, in contrast to the absence of any movement disturbance on day 7 when her plasma level was comparable but her RBC level was appreciably higher. Then as her RBC Li^+ level increased (days 21–23) and her plasma Li^+ remained fairly constant, her TD symptoms decreased. In this case, TD symptom suppression required Li^+ RBC levels approximately equal to 0.31 mEq/liter or greater. The presence of TD symptomatology on day 10 (see figure 1), compared to the greatly reduced TD symptomatology on day 23, can be explained based on Ms. A's increased manic behavior and organic symptoms. Crane and associates (36) report that TD symptoms may be intensified by hyperactivity and agitated emotional states; one would then expect that both the manic behavior and the residual organic symptoms on day 10 enhanced the severity of the TD, which necessitated higher RBC Li^+ levels to obtain a therapeutic effect.

In conclusion, Ms. A's TD symptom suppression occurred while her Li^+ plasma levels remained fairly constant (approximately 0.70–0.75 mEq/liter) and her RBC Li^+ levels increased from 0.21 to 0.31 mEq/liter. Also, the RBC/plasma Li^+ ratio increased correspondingly from 30% to 40%. In this patient the RBC Li^+ levels showed a better correlation than plasma levels in predicting the symptomatic relief of TD. In view of our favorable results, we recommend more research with Li^+ RBC determinations in the management of tardive dyskinesia to further evaluate its clinical usefulness.

Exacerbation of Psychosis by Tricyclic Antidepressants in Delusional Depression

BY J. CRAIG NELSON, M.D., MALCOLM B. BOWERS, JR., M.D., AND DONALD R. SWEENEY, M.D.

The authors describe three patients with delusional unipolar depression whose delusional thinking worsened markedly following administration of tricyclic antidepressant drugs. The patients had met Research Diagnostic Criteria for major depressive episode and had no evidence of schizophrenia or mania. Since tricyclic antidepressants are known to exacerbate psychosis in schizophrenic patients, it is sometimes suggested that the exacerbation of psychotic thinking in depressed patients indicates schizophrenia. The authors suggest that such an exacerbation does not in itself indicate schizophrenia but may occur in patients with an affective disorder who are prone to depressive delusions. The authors discuss the use of antipsychotic medication in this patient group and present a neurochemical hypothesis to explain the interaction of the drug with the illness, which results in exacerbation of psychotic thinking.

TRICYCLIC ANTIDEPRESSANT drugs are known to produce three types of psychotic reactions (1, 2): they can exacerbate psychosis in schizophrenic patients, precipitate mania, or produce a confusional state or toxic psychosis. We will report another clinical syndrome, delusional unipolar depression, in which treatment with tricyclic antidepressant drugs can exacerbate the psychosis.

Delusional unipolar depression appears to be a distinct subtype of unipolar depression. Glassman and associates (3) suggested this because of their observation that delusional depressives have a lower rate of response to tricyclic antidepressants than nondelusional patients. Their review of the literature indicated that previous investigators had also noted a poor response to tricyclic antidepressants among delusional depressives. In a more recent report Quitkin and associates (4) failed to find evidence of a difference in response to imipramine treatment between psychotic and nonpsychotic depressives in a review of data from a study conducted in the early 1960s. The authors suggested that the lack of drug response in previous studies may have resulted from inadequate dosage or duration of drug treatment. It is possible that the difference in findings reported by Glassman and associates and Quitkin and associates is related to the method of selection of patients. In the latter study psychotic patients were selected on the basis of a scale rating of perceptual distortion. It is not clear from the report whether these patients met the criteria for delusional thinking used by Kantor and Glassman (5) or whether some of the patients only had exaggerated depressive concerns.

The question of inadequate dosage has been addressed at least in part in other recent studies (6–8), which have noted lower rates of response in the delusional unipolar patient group even when delusional patients were given a higher dosage of tricyclic (imipramine, 300 mg) (6) or when drug plasma levels were obtained to ensure an adequate therapeutic drug level (7, 8). On the basis of this difference in pharmacologic response it has been argued that delusional unipolar depression may represent a distinct subtype of depression. The three delusional depressives we will describe not only failed to respond to tricyclic antidepressants but suffered an exacerbation of their psychosis after receiving these drugs.

The three patients met the Research Diagnostic Criteria (RDC) for major depressive episode (9). None of the patients had a history of mania. Although they did show evidence of delusional thinking, this appeared to be part of the depressive syndrome. The patients did not show RDC evidence of schizophrenia. The patients were hospitalized on a research unit where daily behavioral ratings (10) were available. All patients were kept drug-free during the first two weeks of hospitalization.

CASE REPORTS

Case 1. Ms. A, a 47-year-old unmarried secretary, was admitted for her first psychiatric hospitalization with the complaint that she could not think and was losing her mind. The patient's difficulties had started 2 years previously after the death of her mother. At first Ms. A experienced withdrawal, self-consciousness; and anxiety. In the 2 months before admission she lost her job, her appetite decreased, she lost weight, felt weak, and slept poorly, her social withdrawal increased, and she felt that her mind was blank and that she

was stupid. Ms. A had had no previous psychiatric treatment. However, at age 35 she had been sufficiently depressed that her ability to work was impaired and her social functioning decreased. On admission she appeared depressed, tense, and mildly suspicious. She thought people had special ideas about her and were going to hurt her. However, after she adjusted to the hospital she was less frightened by these ideas. During the first 2 weeks, which were drug-free, the patient continued to look moderately depressed. At this point she was started on amitriptyline in dosages that were increased to 150 mg over several days. During the first 2 weeks of amitriptyline treatment her depressed mood, irritability, and withdrawal continued. During the third week she noted slight improvement in mood, but her paranoid thinking worsened and was rated as extremely severe. She thought that other patients knew that she was "guilty" and that they were going to dissect her or cut her up. She thought her sister might be hurt and wrote her a note telling her not to visit. There was no change in her orientation, concentration, or memory. This increased paranoid thinking persisted over the next 5 days but responded quickly to trifluoperazine, 8 mg. Treatment continued with trifluoperazine and amitriptyline, 200 mg. Ms. A's mood improved considerably and after 5 weeks on this combination of medications she was considered asymptomatic.

Case 2. Mr. B, a 51-year-old married truck driver, was admitted for his first episode of serious psychiatric illness. His symptoms had started 3 years previously and appeared related to his being placed on part-time status at work. He began experiencing anxiety, apathy, loss of energy, and feelings of worthlessness. He had a brief period of thinking he might be harmed at work but continued to work part-time. In the 6 months before his admission he began to believe that he had cancer and was going to die. In the 2 months before admission he lost 25 pounds, had frequent crying spells and early morning awakening, experienced no pleasure in his activities, and felt helpless and hopeless. He took an overdose of analgesic medication and was hospitalized. On admission Mr. B was markedly depressed and lethargic. There was no evidence of delusional thinking at this point. However, at the end of a 3-week drug-free period evidence of mild paranoid thinking was noted. Amitriptyline was started in dosages increased by 50 mg/day to a maximum of 250 mg. By the fourth day of amitriptyline administration Mr. B's agitation became extremely severe. His paranoid thinking had increased considerably, and he thought he and his family would be killed or harmed. Perphenazine, 24 mg/day, was begun. The patient's level of agitation and delusional thinking diminished rapidly over the next several days. Three weeks after he received the combination of perphenazine, 24 mg, and amitriptyline, 250 mg, Mr. B was still moderately depressed. As a result, the amitriptyline was discontinued and he was started on imipramine, which resulted in noticeable improvement in his depressive symptoms.

Case 3. Ms. C, a 64-year-old woman, had a history of depression beginning at age 55. She had had three hospitalizations early in the course of her illness. Two months before admission her sleep decreased and she experienced early morning awakening. She began to ruminate about her mother and her past. One week before admission she began to experience delusional thoughts that her food was poisoned. She stopped eating and working, stopped caring for her apartment, and withdrew from friends. On admission Ms. C described feelings of guilt, self-reproach, and hopelessness. She appeared agitated but had little spontaneous speech. After an initial drug-free period she was treated with nortriptyline, 150 mg, for 26 days. No improvement was noted, and she continued to appear severely depressed. Nortriptyline was discontinued and imipramine was started in dosages that were gradually increased to 200 mg. Eight days after imipramine was initiated Ms. C became markedly paranoid and extremely agitated. The imipramine was discontinued and she was given 9 ECT, with good response.

DISCUSSION

Previous reports have described a low rate of response among delusional unipolar depressives to tricyclic antidepressants, but exacerbation of psychosis as a result of such treatment has been described rarely. An exception is the observation by Sandifer and associates (11), who reported that tricyclic antidepressant drugs aggravate delusional depression. The three cases we have described demonstrate that tricyclic antidepressant drugs appear to aggravate delusional thinking. Although this may have been merely a worsening of the clinical course of the illness, the temporal relationship suggests that the increase in delusional thinking is a response of the underlying illness to treatment with tricyclic medication. The delusional thoughts that are pharmacologically provoked are consistent with the existing depressive syndrome. Typically, the delusional thinking consists of thoughts of guilt coupled with a paranoid fear that others, knowing of this guilt, will harm the patient. There is no evidence of a toxic delirium or clouding of consciousness. Even during the heightened period of delusional thinking the patient appears neither manic nor schizophrenic. According to Research Diagnostic Criteria, the patient would be designated as having a major affective disorder, psychotic.

The question of whether the development of psychosis during tricyclic treatment in itself suggests schizophrenia is an interesting one. Certainly, the exacerbation of psychosis in schizophrenic patients given tricyclic antidepressants has been well documented in the literature (12–18). Two reports describe the development of psychosis in depressed patients treated with tricyclic drugs. Newman and Fischer (19) described three depressed patients who became overtly psychotic after receiving tricyclic drugs, and they concluded that these medications can push "schizophrenic" patients into psychosis. Two of the patients, however, were 45-year-old men with a depressive syndrome. Apparently they were considered schizophrenic on the basis of the psychosis that developed after tricyclics were administered. In another report Baldessarini and Willmuth referred to the "common clinical impression that latent psychosis may be uncovered during amitriptyline treatment for depression" (20). Their discussion of two cases was interesting in that it described the more florid delusional symptoms as being depressive in nature and consistent with the patient's depressive syndrome. The authors did not sug-

gest these patients were schizophrenic but noted that they might be considered "prepsychotic." Certainly, it is well recognized that severely depressed patients may have depressive delusions, typically with themes of guilt or somatic concern and in some cases associated with paranoid thinking. Exacerbation of these depressive delusions by tricyclic drugs does not in itself indicate schizophrenia but rather a worsening of the affective disorder.

Recognition that tricyclic antidepressants can exacerbate such delusional thinking in depressed patients may help to avoid an inappropriate diagnosis of schizophrenia and also has important treatment implications. We described previously the successful treatment of 12 of 13 patients who had delusional unipolar depression with a combination of tricyclic antidepressants and antipsychotic drugs (21). Exacerbation of delusional thinking was not noted when patients received a sufficient dosage of antipsychotic drug. Implementation of such treatment first requires the identification of patients at risk. It has been our experience that patients who have developed florid delusional thinking following tricyclic treatment have usually presented some evidence of delusional thinking prior to treatment, although it may not have been prominent. Cases one and two in this paper illustrate our experience. A history of episodes of delusional depression or of tricyclic-induced psychosis might also suggest treatment with an antipsychotic-antidepressant combination.

Although a neurochemical understanding of the aggravation of delusional thinking in this diagnostic group is speculative, there is suggestive evidence that patients with this syndrome may have alterations of both dopamine and norepinephrine systems (22), that tricyclic antidepressants may facilitate dopamine systems through an intermediate effect on norepinephrine (23, 24), and that psychotic depressive patients receiving tricyclics may show an increase in CSF homovanillic acid, the major metabolite of dopamine (25). Thus, it is possible that tricyclic antidepressants may aggravate delusional thinking in this patient group through a facilitative effect on dopamine systems.

A Possible Cardiovascular Effect of Lithium

BY ROBERT H. BELMAKER, M.D., RACHEL LEHRER, RICHARD P. EBSTEIN, PH.D., HAYA LETTIK, AND SOL KUGELMASS, PH.D.

Heart rate rises associated with performance of mental arithmetic tasks were compared in 22 euthymic manic-depressive patients receiving lithium carbonate and 17 drug-free normal controls. The lithium-treated subjects showed a markedly lower heart rate response to the mental arithmetic stimulus. No effect was observed on basal heart rate. The results are consistent with lithium's reported inhibition of noradrenaline-induced rises in adenylate cyclase activity but lack of inhibition of basal adenylate cyclase activity. The biochemical and psychophysiological findings may parallel lithium's unique ability to calm excited behavior without sedating normal behavior.

BIOCHEMICAL THEORIES of lithium's mode of action include the possibility that lithium inhibits noradrenergic adenylate cyclase in the brain (1), thus reducing the functional effect of the hypothesized excess of noradrenaline in mania (2). Supporting this possibility is the marked inhibitory effect of lithium on peripheral β-adrenergic adenylate cyclase in man (3). Since lithium has such a marked effect on the peripheral noradrenergic adenylate cyclase, one would expect therapeutic doses to have cardiovascular effects. Fann and associates (4) found the pressor response to noradrenaline reduced by 22% in subjects taking lithium, but a review of the literature did not reveal reports of cardiac slowing or hypotension resulting from lithium use (5). In contrast, hypotensive effects are regularly seen with some phenothiazines and are ascribed to their α-adrenergic blocking effect (6). Since Ebstein and associates (3) reported inhibition of the β-adrenergic adenylate cyclase by lithium, we decided to test its effect on a specifically β-adrenergic cardiovascular function.

Received Oct. 18, 1977; revised March 21, 1978; accepted March 30, 1978.

This investigation was supported in part by a grant from the Israel Center for Psychobiology.

The authors wish to thank Keren Rose for secretarial assistance.

The "mental arithmetic test" is a method of causing consistent, temporary heart rate rises in humans (7–9). The adrenergic receptor involved in heart rate is known to be of the beta type (10), and changes in human heart rate have adrenergic as well as vagal determinants (9, 11). These β-adrenergic receptors are thought to function via adenylate cyclase (3). We therefore chose the mental arithmetic test as a method of inducing heart rate rises in order to compare such rises in lithium-treated and untreated subjects. We predicted that lithium-treated subjects would show a much smaller heart rate rise in response to mental arithmetic tasks than normal subjects. Such a difference would support the concept that lithium in vivo is a physiological inhibitor of noradrenergic function, perhaps in the brain as well as in the heart.

METHOD

The experimental subjects were manic-depressive patients at the lithium clinic of the Jerusalem Mental Health Center. Subjects who had been treated with other drugs in the week prior to examination or whose lithium levels were at toxic or below therapeutic levels were excluded. The mean plasma lithium level of the patients at the determination closest to the time of study (usually later on the same day) was .79 mEq/liter (SEM=±.40). Patients with physical disease, especially cardiovascular, diabetic, hypertensive, or organic brain disease, were excluded. All patients were free of psychiatric symptoms or close to this criterion at the time of study, that is, they were in a euthymic state. Controls were employees of the Jerusalem Mental Health Center who had taken no drugs in the preceding week and who suffered from no physical or mental illnesses. The lithium-treated group included 10 men and 12 women, with a mean age of 42.4 (range, 21 to 63). Controls included 7 men and 10 women, with a mean age of 42.3 (range, 26 to 66). Seven patients had not finished high school, 7 had finished high school only, and 8 had had some education beyond high school. None of the control subjects had not finished high school, 5 had finished high school only, and 12 had had post-high school education.

The mental arithmetic tasks were similar to those of Lacey and associates (7) and Tursky and associates (8). Each of the four tasks demanded mental effort and concentration; to avoid introducing anxiety as a possible factor, no time limits were set.

0002-953X/79/05/0577/03/$00.40 © 1979 American Psychiatric Association

Patients and control subjects were introduced to the experimenter in a quiet room by the clinic director (R.H.B.). They were told in advance that they were to be given a test of heart rate. After 3–10 minutes to acquaint themselves with the procedure, subjects were attached to a middle finger photoelectric transducer. The transducer was connected to an analog chart recorder that continuously recorded heart rate at each beat. The subjects were asked not to talk during the experimental trials; all responses were written with the unattached hand.

The first task was to count backward mentally from 100 to 50 and to signal "finish" with the free hand when done. The second task consisted of 23 simple addition problems, in which the subject was asked to add 4 to one number and subtract 3 from the next number in an alternating fashion. The third task comprised 15 multiplication problems at two levels of difficulty. The "hard" set was given to high school graduates and the "easy" set to nongraduates. The fourth task was a modification for use in Hebrew of Lacey and associates' "reverse spelling task," during which the experimenter read aloud 17 common words and the subject was asked to reverse the letters of the word and write down the result.

Each task was presented on a sheet of paper that the subject held on his knees. The answers were written on the same paper. Between each task the next task was explained; this interval was about 50 seconds. After the last task the subject was asked to sit quietly for 30 to 60 seconds, and a "baseline heart rate" was recorded when heart rate ceased to decline more than one beat per minute over a 15-second period. The total procedure took from 10 to 20 minutes for each subject.

Heart rates for each task period were determined by counting 15 seconds from the onset of the task (on the recorded tape) and then averaging the following three instantaneous heart rates at 5-second intervals. Each subject thus had an average heart rate for each of the four tasks. Heart rate in the final rest period was calculated as the mean of the three instantaneous heart rates at 5-second intervals after heart rate ceased to decline more than one beat per minute over a 15-second period. Data were analyzed by using the final rest period as baseline and calculating increases by subtracting the subject's "resting" heart rate from the heart rate associated with each task.

RESULTS

Table 1 shows the rise in heart rate with the various mental arithmetic tasks in the lithium-treated and untreated subjects. There is no significant difference between the two groups in "rest period" heart rate. The lithium-treated subjects show a consistently smaller increase in heart rate with each task than the control subjects.

Analysis of the results by sex show no differences in the rise between sexes. Splitting the lithium-treated group into 15 patients with high school education or greater and 8 patients with less than high school education revealed no effect of education on the heart rate response to any of the tasks. There was no difference in heart rate response between those who received the "hard" and those who received the "easy" versions of task three. There was no difference in the percentage of correct answers between the lithium-treated and untreated groups; all subjects gave over 85% correct responses in every task.

TABLE 1
Heart Rate Increases[a] During Mental Arithmetic Tasks In 22 Lithium-Treated and 17 Untreated Subjects

Task	Lithium Group		Untreated Group		Significance[b]
	Mean	SEM	Mean	SEM	
Counting backward	3.5	1.7	7.4	1.7	p=.07
Addition problems	6.8	1.0	12.9	1.7	p<.05
Multiplication problems	7.3	1.2	12.8	1.8	p<.05
Reverse spelling	4.4	.7	11.2	1.8	p<.05

[a]In beats per minute over mean resting heart rate (lithium group=78.4±2.4 SEM; untreated group=80.7±2.9 SEM; difference is not significant).
[b]One-tailed Student's t test.

DISCUSSION

These results suggest that treatment with lithium inhibits the cardioacceleration induced by various mental arithmetic tasks. This result is consistent with the interpretation that lithium inhibits noradrenergic adenylate cyclase and thus inhibits the function of the sympathetic nerves to the heart. Misu and associates (12), in studying isolated rabbit sympathetic nerve-heart preparations, found that lithium perfusion blocked the heart rate response to electrical stimulation of the nerve. It is of interest that in our experiment the effect of lithium is seen only on the cardioacceleratory response and that lithium-treated subjects do not show a reduction in baseline heart rate. That is, lithium seemed to block activation without affecting baseline activity. This may explain why lithium can block mental arithmetic-induced increases in heart rate and the pressor response to infused noradrenaline (4), yet does not cause cardiovascular side effects (5) due to interference with "basal" sympathetic activity. A similar phenomenon may also be apparent on the biochemical level, where lithium inhibits the noradrenaline-induced activation of adenylate cyclase but does not reduce basal activity levels of the enzyme (1, 3, 13). If such mechanisms occur similarly in brain noradrenergic systems that affect mood and behavior, the paradox of lithium's calming effect in mania but absence of a sedating effect in normal or euthymic individuals could perhaps be understood (14).

The results of this study might have significance for understanding lithium effects beyond the use of the

cardiac sympathetic nerve as a peripheral model for what might occur in brain noradrenergic systems. The James-Lange theory of emotion (15) suggests that peripheral arousal contributes importantly to the brain's perception of emotion. If the pressure of thinking and speech in mania causes cardiac acceleration, lithium treatment would tend to block this effect. A vicious cycle of central activation, peripheral arousal, and feedback central activation might thereby be interrupted.

One possible weakness of our study is the fact that all of the lithium-treated subjects were manic-depressive patients, whereas all untreated subjects were psychiatrically normal. Attempts to increase the comparability of the two groups included use of only those patients who were in a euthymic or nearly normal state; choice of an untimed mental arithmetic test, which is probably less affected than timed tests by anxiety, personality, or other extraneous factors (7, 8); statistical analysis to show that educational level had no effect on heart rate response; and demonstration that both groups had equivalent degrees of attentiveness, as measured by proportion of correct responses. The present results are therefore consistent with the theory that lithium is an inhibitor of noradrenergic neurotransmission, and especially of noradrenergic activation beyond basal levels.

Effects of lithium on heart function in patients with cardiac disease have recently been reviewed (16). Whereas some cardiac arrhythmias may be exacerbated by lithium, other arrhythmias, including paroxysmal atrial tachycardia, may be ameliorated (17). The present results suggest the value of controlled study of the prophylactic use of lithium for paroxysmal atrial tachycardia, especially in those cases in which the heart is otherwise healthy and the cardiac nerves (due to psychosomatic factors) may initiate the attacks of elevated heart rate.

The Quantitative Measurement of Depression and Anxiety in Male Alcoholics

BY JOHN E. HAMM, M.D., LESLIE F. MAJOR, M.D., AND GERALD L. BROWN, M.D.

Depression and anxiety have been reported to be commonly associated with alcoholism. Most attempts to clarify this relationship have suffered from a patient selection bias in that only those alcoholics who sought treatment were studied. The authors performed quantitative measurements of depression and anxiety in a group of 48 men referred for treatment solely on the basis of excessive drinking. The prevalence of depression and anxiety as measured by both the Zung and Hamilton scales was lower than that shown in previous studies. The results of this study indicate that clinical depression and anxiety are not common problems in young, healthy male alcoholics.

APPROXIMATELY NINE MILLION Americans suffer from alcoholism, a progressive illness with early, middle, and late stages (1) characterized by psychological, social, and physical symptoms. Both depression and anxiety are commonly seen among alcoholics (2–4), but their interrelationships are unclear. Menninger (5) conceptualized alcohol addiction as a chronic progressive suicide. Alcoholics, like depressives, have a higher incidence of suicide than the normal population (1, 6, 7). Some reports note that severe drinking leads the alcoholic into a precarious life position beset with many real object losses that result in the emergence of depressive affects (6–8). Other studies stress the antidepressant psychopharmacologic effects of acute alcohol ingestion (9–11). Investigators who study neuropharmacologic effects of alcohol suggest that chronic alcohol ingestion leads to depletion of neurotransmitters, thereby causing depression (12–15). A genetic basis for alcoholism and a genetic relationship between alcoholism and affective disorder have also been proposed (4, 16, 17).

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977; received July 5, 1977; revised Dec. 8, 1977; accepted Jan. 10, 1978.

When this work was done, Dr. Hamm was Chief Resident, Department of Psychiatry, National Naval Medical Center, Bethesda, Md.; he is now Chief of Psychiatry, Naval Regional Medical Center, Bremerton, Wash. 98314. Dr. Major is Clinical Investigator and Dr. Brown is Clinical Investigator, National Institute of Mental Health, Bethesda, Md. 20014.

The authors would like to thank Ms. Marcia D. Minichiello, Research Assistant, Biological Psychiatry Branch, NIMH, for assistance in data analysis.

Alcoholics who seek treatment and suffer from alcohol-related physical illnesses and/or psychosocial problems usually comprise the study groups reported in the literature. Our sample was referred solely for problems of excessive drinking without the complications of associated medical and/or significant psychiatric problems. Studying such samples may help to clarify the relationship between alcoholism, depression, and anxiety.

METHOD

The study was conducted on the Alcohol Rehabilitation Unit of the National Naval Medical Center, Bethesda, Md. All patients admitted to this 15-bed unit completed a six-week structured program, which included mandatory participation in Alcoholics Anonymous. These patients, all active duty male military personnel, were referred by supervisors, physicians, or alcohol counselors. Inclusion criteria were as follows: 1) age between 20 and 45 years; 2) no significant medical or psychiatric problems; 3) a score of more than 6 on the Michigan Alcoholism Screening Test, a widely used 25-item yes-no questionnaire (18, 19); and 4) no borderline or psychotic condition or organic brain syndrome, as determined by the Research Diagnostic Criteria (RDC) (20, 21) and by psychiatric, psychological, and medical assessments, when indicated.

The 48 subjects had a mean age of 32 (SD=7.9). There was a family history of alcoholism in 70.8% of the sample. Lineal family history was positive for major affective disturbance in 13.8% and for suicidal behavior in 16.2%. The duration of excessive use of alcohol (more than 2,000 ounces of absolute alcohol per year) ranged from less than 1 year to 17 years (mean=5±4.5). Eight patients experienced mild withdrawal symptoms. Within 48 hours of admission, the patients completed the Zung Self-Rating Depression Scale (SDS) and Self-Rating Anxiety Scale (SAS) (22–24). Raw scores were converted to index ratings based on 100. Within 72 hours of admission, the patients were rated on the Hamilton Depression Scale (HDS) and the Hamilton Anxiety Scale (HAS) (25–27). All rating scales were completed again at 3 weeks and at 6 weeks after admission. Some patients did not complete all of the self-rating scales at the designated rating times because the treatment program schedule made them unavailable. Likewise, some patients were

TABLE 1
Depression and Anxiety Scores at Three Periods for Alcoholics in Treatment

Scales	Baseline			3 Weeks			6 Weeks[a]		
	N	Mean	SEM	N	Mean	SEM	N	Mean	SEM
Hamilton Depression Scale	48	10.0	0.9	41	7.7	0.8	33	6.3	0.7
Hamilton Anxiety Scale	48	5.8	0.6	41	4.9	0.5	33	4.4	0.8
Zung Self-Rating Depression Scale	46	44.7	2.0	46	40.0	1.8	44	36.7	1.4
Zung Self-Rating Anxiety Scale	46	43.8	1.6	45	37.7	1.4	44	36.5	1.2

not available for interview at all of their designated interview points. This is reflected in the varying Ns as seen in table 1.

RESULTS

None of the 48 patients scored above 25 (the cutoff point for severe depression) on the baseline HDS, and only 3 scored above 22 (6.3% of the group). Scores of 22–25 are indicative of depression in inpatients (25, 28). There are currently no standardized values for HAS. Mean HDS and HAS baseline, 3-week, and 6-week scores are summarized in table 1. The mean values for the SDS and SAS are also summarized in table 1. At baseline 34.8% of the group scored above 50. Zung cited a score of 50 as indicating depressive affect and noted the following means: 64 for inpatients, 33.8 for normal controls. By 6 weeks only one individual had a score above 50 and the group mean SDS was 36.5.

As all raw data were approximate values obtained from ratings, Spearman rank-order correlation analyses were applied to the data. There were significant HDS-SDS and HAS-SAS correlations at baseline and 3 weeks, but neither correlation was significant at 6 weeks. The HDS and HAS and the SDS and SAS were significantly correlated ($p<.01$) at all three rating points. No significant correlations were found between any rating scale scores and age, duration of excessive drinking, or amount of alcohol consumed.

DISCUSSION

The prevalence of depression and anxiety in this study is lower than that found in previous studies (2, 29–33). Except for 3 patients, the initial HDS study group scores were all lower than the cutoff range used to identify depressives. More than a third (34.8%) of the group scored above 50 on the baseline SDS, but scores similar to these were reported by Zung and associates (34) for personality disorder, anxiety reaction, and transient situational disturbance. The results of this study indicate that depression and anxiety in the clinical range are not common among young, healthy alcoholics. Thus, our findings are not consistent with the hypothesis that alcoholics are basically depressed individuals who drink to alleviate their dysphoria. A possible explanation for the low incidence of depression we found is that few of these patients had suffered alcoholism long enough to result in major life losses or that they simply had a lower "loss risk" because of their age. Holmes and Rahe (35) have shown that major life changes are associated with an increased incidence of physical and psychiatric problems. Depression is more common in older people in general (36) and may be more common in older or later stage alcoholics who have suffered more medical and/or psychosocial consequences of alcoholism and/or age. Similarly, if depression secondary to alcoholism were related to chronic depletion of neurotransmitter stores, this study group would be at less risk than an older sample. No correlation between depression and length of drinking was noted; however, the age distribution within this study group would bias against such a finding.

The present study raises the possibility that previous studies reporting a high incidence of depression in alcoholics (2, 29–33) used biased samples of alcoholics, e.g., those in need of medical or psychiatric hospitalization or those with coincident conditions that would lead to spurious positive correlations. Partial confirmation for these possibilities comes from a study in which Woodruff and associates (37) compared alcoholics who seek psychiatric treatment with those who do not. The nature of alcoholism in the two groups was similar. Depressive symptoms and the presence of secondary affective disorder clinically distinguished the two groups. The alcoholic who does not seek treatment is probably more similar to the group we studied and, perhaps, to the majority of alcoholics in the general population.

The positive correlation between the HDS and SDS is similar to the finding of Brown and Zung (38) for these two rating instruments. The lack of correlation at the 6-week comparison probably has no clinical meaning; values on both scales were quite low and the mathematical corrections for tied values in the Spearman rank-order correlations were much more extensive than would be the case with broader ranges of values. The entire range of HDS-SDS values for this population was somewhat narrow and could not have been used to reassess the earlier finding (38) that HDS scores increase at a slower rate than SDS scores among severely depressed patients. In the present

study, a higher rating for depression was seen on the SDS than the HDS. The cutoff point of 50 for the SDS was derived from an outpatient population with mixed psychopathology. The HDS was standardized using an inpatient population of depressed patients.

CONCLUSIONS

Previous studies of alcoholics have found a high incidence of co-existing depression, and this finding had led to a number of hypotheses. Relatively little attention has been paid to possible patient selection bias. Often, such studies relied on patients who were in urgent need of medical and/or psychiatric care, although such patients may not be representative of alcoholics in the general population. The patients in our study were selected by others as being suitable for rehabilitation from alcohol abuse and did not have significant medical or psychosocial problems. Depression and anxiety were not common problems for this group. Further studies, with close attention to methods of patient selection, are necessary to clarify the relationship between alcoholism, depression, and anxiety.

Bipolar Illness: Factors in Drinking Behavior

BY DAVID L. DUNNER, M.D., BRUCE M. HENSEL, AND RONALD R. FIEVE, M.D.

Alcohol use and abuse was investigated in 73 patients with bipolar I manic-depressive illness who were attending a lithium clinic. Alcohol-related problems were identified in 7 of the male and none of the female patients. Family data revealed a higher morbid risk for alcoholism among relatives of patients with drinking problems than among relatives of patients without drinking problems. Morbid risks for affective disorder for these two groups of relatives were similar, suggesting that alcoholism among relatives of patients with bipolar illness is not solely "genotypically" related to the affective disorder.

THE PURPOSE of the study described in this paper was to investigate alcohol use among a well-defined group of manic-depressive (bipolar I) patients and to determine if alcohol-related problems in these patients were associated with alcoholism in their relatives. Increased alcohol intake during manic and depressive states is often observed. This subject was reviewed by Freed (1), who cited several reports indicating increased alcohol intake during depression. Morrison (2) studied the drinking behavior of patients admitted to a Veterans Administration hospital for mania and found that a high percentage of such patients were heavy drinkers, although a secondary diagnosis of alcoholism among these patients was no more frequent than among patients with other psychiatric disorders admitted to the same hospital.

Evidence for a genetic factor in the etiology of alcoholism was recently reviewed by Goodwin (3). Goodwin described a subgroup of alcoholics whose illness had an early onset and who had strikingly positive family histories of alcoholism. Although an increased risk for alcoholism is frequently found among relatives of bipolar patients (4, 5), the relationship of alcoholism in such families to drinking problems among the bipolar patients themselves has not been studied.

Presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8-12, 1978. Received Jan. 3, 1978; revised March 31, 1978; accepted April 6, 1978.

This study was supported in part by Alcohol, Drug Abuse, and Mental Health Administration grant MH-21586 from the National Institute of Mental Health and by the Columbia/Millhauser Depression Center Grant.

METHOD

The subjects studied were attending the lithium clinic of the New York State Psychiatric Institute. All of the patients met diagnostic criteria for primary affective disorder (6), and all of the patients were subclassified as having bipolar I affective disorder because they had been previously hospitalized for mania (5). Patients voluntarily consented to participate in the study, which was conducted over a four-month period. All bipolar I patients who attended the clinic during the study interval participated. The selection criteria for treatment of patients in the clinic excluded from the study patients who had severe drinking or drug problems. For example, patients with bipolar illness who had histories of alcohol addiction resulting in treatment for alcoholism were screened out at the initial evaluation.

The patients were asked to complete a questionnaire regarding their current and past drinking behavior. This form included all items pertinent to the diagnosis of alcoholism in a structured interview (7) based on the criteria of Feighner and associates (6). Responses to the questionnaire were reviewed with the patient by one of us (B.M.H.) and were also confirmed by review of responses to similar questions recorded during the structured interview.

A subject was considered to have (or to have had) drinking problems if he had three or more alcohol-related symptoms, which included social (job, marriage, legal), psychological, and medical problems that a physician and/or the patient attributed to alcohol. The specific symptoms examined were derived from the criteria of Feighner and associates (6) for alcoholism. None of the patients met these criteria for alcoholism.

Family histories were obtained through systematic interviews of the patients and, in many cases, through structured interviews of relatives. Only data regarding parents and siblings were included. The total number of relatives studied was 371. Of these, 310 were still living; 154 were interviewed directly.

Diagnosis of alcoholism in a relative was made through blind review of the structured interview records using the criteria of Feighner and associates (6) or by information from the proband or other relatives.

0002-953X/79/05/0583/03/$00.40 © 1979 American Psychiatric Association

The problems related to drinking in these latter cases also had to be severe enough to result in social, medical, or psychological complications. A relative was diagnosed as alcoholic through family history only if the history was confirmed by at least two family members. Family history data were determined independently of the alcohol status of the patient. Morbid risk data for alcoholism were calculated using the ages at risk from Amark (8).

Family history of affective disorder was determined from blind review of the structured interviews or family history data, and affectively ill relatives were diagnosed according to the criteria of Fieve and Dunner (9). Morbid risks for bipolar and unipolar illness were calculated by considering relatives who had not been treated for primary affective disorder as not psychiatrically ill and by using the ages at risk for bipolar II illness and unipolar illness previously determined by a review of age-of-onset data from our patients (D.L. Dunner, unpublished data).

RESULTS

There was good agreement between the reports of drinking behavior from the questionnaire and the structured interview. Of the 73 patients studied, 36 were women and 37 men; 27 of the women and 28 of the men drank socially. Alcohol-related problems were identified in 7 of the men and none of the women. This difference was statistically significant ($\chi^2=5.48$, $p<.02$). The differences in mean ages of the groups (women, 43.9±16 years; men without drinking problems, 48.8±15.3 years; men with drinking problems, 44.6±14.8 years) were not statistically significant.

Among the 7 patients with drinking problems, the alcohol-related symptoms identified most frequently were missed work, difficulty with family or friends, driving problems, problems with the police, blackouts, and physical violence while drinking. Each of these symptoms except physical violence was reported by 4 patients; physical violence was noted by 3 patients.

Morbid risk for alcoholism was significantly higher in relatives of patients who had drinking problems than in relatives of patients without drinking problems (see table 1). Furthermore, relatives of men without drinking problems showed a significantly lower morbid risk for alcoholism than relatives of women patients. There was no significant difference when relatives of all male and all female patients were compared for alcoholism. Thirteen of the relatives of women were identified as alcoholic. Six of these relatives were male and 7 were female. Two of the 3 alcoholic relatives of males without drinking problems were male, as were all 5 alcoholics related to male patients with drinking problems.

Morbid risks for affective disorder among relatives were comparable in the patient groups (see table 2). Overall, 17 of 164 male relatives of patients without drinking problems had affective disorder as compared to 2 of 22 male relatives of patients with drinking problems. Similarly, 39 of 174 female relatives of patients without drinking problems had affective disorder as compared to 2 of 11 female relatives of patients with drinking problems.

TABLE 1
Family History of Alcoholism of 73 Bipolar I Patients

Patient Group	Relatives: Number Studied	Relatives: Number at Risk	Relatives: Morbid Risk %
Men with drinking problems (N=7)	33	20.2	24.9[a]
Men without drinking problems (N=30)	151	101.8	2.8
Women (N=36)	187	122.5	10.2

[a]Significantly higher than relatives of men without drinking problems ($\chi^2=9.87$, $p<.01$).

DISCUSSION

We found that 7 of our 37 male patients (approximately 19%) had histories of problems related to alcohol. Other studies of alcoholism and/or alcohol-related problems among manic-depressive patients reveal incidences of alcoholism of 20%–40% (1, 2). Many of these studies were done on patients who were diagnosed as having affective illness by criteria less rigorous than those applied to our sample. Since our clinic sample was prescreened to exclude alcoholics, our data suggest that there would be considerable overlap of alcohol-related problems in a bipolar I population not prescreened to exclude such problems.

The morbid risk for alcoholism is increased among relatives of patients with alcohol-related problems as compared to relatives of patients without such problems. Although environmental factors are implicated in the etiology of both alcoholism and affective disorder, recent data suggest the importance of genetic factors in the development of these illnesses (3, 4, 10). Thus it is likely that the alcoholism found among relatives of patients with drinking problems is occurring on a genetic basis or, conversely, that patients who have family histories of alcoholism are likely to have symptoms of alcoholism.

There has been some controversy regarding whether alcoholics found among relatives of bipolar I subjects should be considered to have the affective "genotype." Our data suggest that most of the alcoholism seen in relatives of male bipolar I patients may be genetically unrelated to the affective disorder, since the morbid risks for affective disorder were similar among relatives of patients with and without drinking problems. Morrison (2) also interpreted his data as indicating that alcoholism and primary bipolar affective disorder may be independently caused. His population was 90% male. Further support of the hypothesis that alcoholism and primary affective disorder may be genetically unrelated could be shown by studying the rel-

TABLE 2
Primary Affective Disorder Among Relatives of Bipolar I Patients With and Without Alcohol Problems

Patient Group	Male Relatives			Female Relatives[a]		
	Number	Bipolar Illness Morbid Risk %[b]	Unipolar Illness Morbid Risk %[b]	Number	Bipolar Illness Morbid Risk %[b]	Unipolar Illness Morbid Risk %[b]
Men with drinking problems	22	9.6 (1/10.4)	8.6 (1/11.6)	11	15.7 (1/6.4)	14.4 (1/7.0)
Men without drinking problems	74	9.1 (4/44.0)	8.2 (4/48.7)	77	11.3 (6/53.0)	17.2 (10/58.2)
Women	90	12.2 (6/49.3)	5.4 (3/55.3)	97	14.5 (8/55.0)	21.8 (15/68.8)

[a]There were no significant differences among male or female relatives for the different patient groups.
[b]Numbers in parentheses refer to the ratio of number ill to number at risk.

atives of a large population of women with bipolar illness who also have drinking problems. Unfortunately, no such women were found in this sample. The hypothesis would predict that relatives of such women should have elevated morbid risks for alcoholism but similar risks for primary affective disorder as compared to the results obtained from the women patients in this study. Data from other centers regarding this problem would be of interest.

Are All Recently Detoxified Alcoholics Depressed?

BY MARTIN H. KEELER, M.D., C. INGA TAYLOR, M.D., AND WILLIAM C. MILLER, M.D.

Reports of the prevalence of depression among alcoholics vary from 3% to 98%; the authors attribute this variation to the use of different diagnostic criteria. They used clinical diagnosis, the Hamilton Depression Rating Scale, the Zung Self-Rating Depression Scale, and the MMPI to diagnose 35 men recently withdrawn from alcohol. The percentages of depression diagnosed were 8.6%, 28%, 66%, and 43%, respectively. The authors point out that the Hamilton, Zung, and MMPI scales are not diagnostic of depression in themselves and that accurate diagnosis of depression in alcoholics will reduce inappropriate treatment of nondepressed alcoholics and ensure careful treatment of the truly depressed.

WE STUDIED the prevalence of depression in 35 men recently withdrawn from alcohol, using the following criteria: clinical diagnosis, the Hamilton Depression Rating Scale (1), the Zung Self-Rating Depression Scale (2), and the Minnesota Multiphasic Personality Inventory (MMPI). The study was designed to compare the effects of using different criteria to diagnose depression among alcoholics rather than to determine the absolute prevalence of depression among alcoholics, which would require a sample stratified so as to include different settings and populations.

The results of using different criteria are important for two reasons: 1) reports of the prevalence of depression among alcoholics vary from 3% to 98%, which obviates any understanding of the relationship between them, and 2) reports of high rates of depression among alcoholics have in the past led to the use of antidepressant drugs as treatment for alcoholism independent of any specific evidence of depression. The diagnosis of depression among alcoholics has been accepted as a reason to use tricyclic antidepressants and is of immediate clinical, in addition to theoretical, relevance. This has been only slightly modified by using criteria for depression that would apply to virtually the entire population of alcoholics.

These trends have run their course; however, the availability of lithium as a treatment for mania and perhaps for depression, as a prophylaxis against manic and depressive episodes in patients who have bipolar illness, and as a possible prophylaxis against depressive episodes in unipolar depressive illness could readily lead to the administration of lithium to almost all alcoholics. This could occur if alcoholism were equated with depression or if overinclusive diagnostic criteria were used.

PREVIOUS ESTIMATES OF THE PREVALENCE OF DEPRESSION IN ALCOHOLICS

Winokur and associates (3), using data from structured interviews as the criteria, reported a figure of 3% primary affective disorder among males treated for alcoholism. Shaw and associates (4), accepting as criteria elevation in the Zung Self-Rating Depression Scale (2), the Beck Depression Inventory (5), or the depression scale of the MMPI reported a prevalence of depression of 98% among patients requesting treatment at a halfway house. Weingold and associates (6) reported that 72% of those admitted to a state hospital alcoholism program could be diagnosed as depressed by the Zung scale. Rosen (7) reported the group mean of the depression scale of the MMPI to be significantly elevated for a group of male patients admitted to the UCLA Alcoholism Clinic and for a group of skid-row alcoholics.

Three studies (4, 8, 9) have evaluated the use of tricyclic antidepressants alone or with benzodiazepines as treatment for alcoholism, although in only one of the studies (4) were changes in depression systematically ascertained.

METHOD

Our subjects were male alcoholics consecutively admitted to the alcoholism treatment service of a Veterans Administration hospital. Of 39 patients admitted, 35 completed the protocol. All were withdrawn from alcohol by the use of decreasing doses of chlordiazepoxide or diazepam. All of the diagnostic methods were applied between the fifth and seventh days after admission. No other psychotropic medication was administered before the completion of evaluation.

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977. Received Sept. 9, 1977; revised Dec. 2, 1977; accepted Feb. 10, 1978.

Dr. Keeler is currently Director, Alcoholism Treatment Program, Veterans Administration Hospital, 2002 Holcombe Blvd., Houston, Tex. 77211, and Professor of Psychiatry, Baylor College of Medicine.

0002-953X/79/05/0586/03/$00.40 © 1979 American Psychiatric Association

Clinical diagnoses based on *DSM-II* criteria were made at case conferences in which the patients were interviewed in the presence of the attending staff. The Hamilton Depression Rating Scale (1) was administered by a psychiatrist. This test is widely used in studies of depression, but Hamilton stated that the scale should not be used to diagnose depression, although it can measure changes in depression.

Likewise, Zung did not comment directly as to whether there is a cutoff point on the Zung Self-Rating Depression Scale (2) at which depression may be diagnosed but emphasized the ability of the scale to compare populations and to measure change. The developers of the MMPI (10) stated that elevations in any scale are not in themselves diagnostic of that entity. We included the MMPI in this study because other studies have reported MMPI means for alcoholics.

RESULTS

Table 1 summarizes the results of our study. If clinical diagnosis is used as the criterion for depression, only 8.6% of the 35 alcoholics we studied were depressed. The Hamilton Depression Rating Scale has no cutoff point for depression and has not been used by others as a test for depression among alcoholics. We selected a score of 20 as a cutoff point on the basis of a study of mean values in groups of depressed patients (11) that used the Hamilton and Zung scales. By this criterion, 28% of the group in our study were depressed. Weingold and associates (6) used a score of 44 on the Zung Scale in their study of the prevalence of depression among alcoholics. By this criterion, 66% of the patients in our study were depressed. The group mean of the depression scale of the MMPI was 71.3, and 43% of the patients had scores exceeding 70. The Spearman correlation coefficient (.56) between the MMPI and Zung results was significant ($p<.0005$). The correlations between the Hamilton and Zung (.25) and the Hamilton and the MMPI (.27) were not significant.

TABLE 1
The Prevalence of Depression Among Recently Detoxified Alcoholics (N=35)

Diagnostic Method	Depressed Patients (%)	Score	
		Mean	SD
Clinical diagnosis	8.6		
Hamilton Depression Rating Scale (20+)	28	13.2	7.4
Zung Self-Rating Depression Scale (44+)	66	49.8	12.2
MMPI depression scale (70+)	43	71.3	17.1
MMPI or Zung	69		

DISCUSSION

This study of the prevalence of depression among recently detoxified alcoholics replicates the disparate results reported by others. The difference is that in our study it is obvious that the varying results depend on the criteria used to diagnose depression. The 8.6% prevalence based on clinical diagnosis is similar to the 3% prevalence based on data derived from structured interviews in the study of Winokur and associates (3), although the bases for diagnoses differ. It is possible for a structured interview to detect evidence of recurrent affective disorder when it is in remission. It is also possible for clear-cut evidence of manic or depressive episodes to be present without the patient's history suggesting such disorder. The similarity between this study and that of Winokur and associates is that each reports a low prevalence of depression among detoxified alcoholics.

The mean for the depression scale of the MMPI is above 70 in our study and in Rosen's study (7). The Zung scale diagnosed 66% as depressed in our study and 72% as depressed in the study of Weingold and associates (6). Comparison with the study of Shaw and associates (4) is difficult because we did not use the Beck scale. Nevertheless, the 71% diagnosed as depressed by either the depression scale of the MMPI or the Zung scale is impressive.

There is no shortage of factors that could account for the disparate results. The depression scale of the MMPI is in itself not diagnostic of depression. The results of the MMPI are expressed in patterns rather than in single-scale elevations. The F scale of the MMPI, which measures confusion and/or random answering of questions, was as significantly elevated (70.6) as the depression scale. Some confusion in a population would be expected immediately after alcohol withdrawal that in turn followed a period of excessive drinking. Many of the MMPIs are invalid due to this confusion. There is no validation scale for the Zung, but manifest inability to produce a valid MMPI gives reason to question the validity of the Zung.

Carroll and associates (11) reported a critical comparison of the ability of the Zung and Hamilton scales to distinguish between populations of depressed patients who were hospitalized on a psychiatric ward, cared for in a day hospital, and treated in a general practice clinic. The Hamilton but not the Zung separated the groups. This result raises a question about whether the Zung scale can distinguish differences in the severity of depression among patients, although it does not impugn the ability of the device to measure changes within an individual.

Hamilton stated specifically that his scale does not diagnose depression because diagnosis depends on the presence of signs and symptoms of a condition and the absence of evidence of other conditions. The results of chronic alcoholism, a recent period of excessive drinking, and recent alcohol withdrawal can produce responses to items of the Hamilton scale that do not indicate depression. Zung made no such reservations about his scale, but we believe that the same principle applies.

The mean for the most elevated items on the Zung scale was above three on a four-point scale, with one defined as absent or minimal. These items were 1) not enjoying the company of attractive women, 2) diminished eating, 3) less hope for the future, 4) difficulty in making decisions, and 5) not feeling useful and needed. The mean for the least elevated Zung items was below two on a four-point scale. These were 1) crying spells or feeling like crying, 2) weight loss, 3) constipation, 4) tachycardia, 5) irritability, and 6) thinking "others would be better off if I were dead." The mean of the five high items and complete denial of all of the other items in the Zung scale would give a value diagnostic of depression. Not feeling useful and needed, eating less, and lacking hope for the future are consistent with the reality situations of the populations studied. The high Hamilton items are those for which the mean is above one on a five-point scale with zero defined as absent. We noted only those items rated on a five-point scale and reports of sleep disturbance adjusted to such a scale. Depression, guilt, somatic evidences of anxiety, report of sleep disturbance, and hypochondriasis are the high items. The low Hamilton items, those for which the mean was less than one-half with zero as absent and one as mild, are suicidal tendencies and agitation. This pattern is more suggestive of marked depression than is the Zung pattern, but the means are much lower.

The psychiatric diagnoses given to our subjects were all of psychotic rather than neurotic depression. All of the patients so diagnosed were treated with tricyclic antidepressants; no other patients in the study were so treated. It is likely that in other situations some other patients would have been considered to have neurotic depression.

CONCLUSIONS AND SUMMARY

A rather troubling conclusion is that the diagnosis of depression in an alcoholic population by rating scales alone is almost as inclusive as considering all alcoholics to be depressed. This can have two effects, the first and more obvious of which is the widespread use of inappropriate treatment. The second and more subtle effect is the failure to detect the considerable number of individuals who are truly both alcoholic and depressed and require careful treatment with appropriate medication.

The difference between 3% and 98% of affective disorder in alcoholics in other studies is matched by the range from 8.6% to 71% in our study. The figure depends on which diagnostic criteria are used. Many obvious factors account for this result. These include diagnosis by devices either not claimed to be diagnostic (the MMPI and Hamilton scale) or whose use without clinical verification has been questioned (the Zung scale). A significant factor may be that the sequelae of chronic alcoholism and/or a recent prolonged spell of excessive drinking and/or recent alcohol withdrawal can produce signs and symptoms similar to those of depression and invalidate self-administered tests. This result is of critical importance if the diagnosis of depression leads to treatment with tricyclic antidepressants or lithium. However, there are indeed many alcoholics who have the types of affective disorders that require such treatment.

It must be emphasized that studies of the relationship between affective disorder and alcoholism which are based on a sample biased by demographic factors such as ethnicity, social standing, region, and the method of subject location do not give accurate measures. Nevertheless, within any one study the differences in rate that depend on the criteria for diagnosis are valid.

Family Rituals and the Recurrence of Alcoholism Over Generations

BY STEVEN J. WOLIN, M.D., LINDA A. BENNETT, PH.D., AND DENISE L. NOONAN

There have been relatively few attempts to identify environmental factors in the transmission of alcoholism across generations. Using the framework of family systems theory, the authors examined the extent of change in family rituals in 25 families in which at least 1 parent was or had been an alcoholic. They found that families whose rituals were altered during the period of heaviest parental drinking were more likely to evidence transmission of an alcohol problem to the children's generation than families whose rituals remained intact.

OUR OBJECTIVE in this paper is to report the results of a family study assessing the impact of the maintenance of disruption of family ritual on the recurrence of alcoholism over generations. Jellinek (1) and Winokur and associates (2), among others, have documented the frequent incidence of alcoholism across generations of families. However, to date there is little evidence based on research to explain why alcoholism transmission occurs in some families but not in others. The studies of Goodwin and associates of adoptees of alcoholic biological parents in Denmark (3, 4) suggested that genetic factors may play a role in the development of chronic and severe alcohol problems over generations of families. In contrast, few attempts have been made to identify environmental factors—those associated with family life, for example—that are clearly related to alcoholism transmission.

In this research we looked to the family's psychosocial environment to explain the continuity of alcoholism over generations. Our work is grounded in family systems theory, which views the family unit as the locus of pathology in the sense that the pathology is so intertwined with ongoing family functioning that the problem cannot be isolated from the rest of family interaction and behavior.

Applying the systems concept to alcoholic families, Ewing and Fox (5) described the alcoholic marriage as a homeostatic mechanism that strongly resists change. Ablon (6) suggested,

> If the family is considered as a social system with interdependent parts consisting of interacting personalities with each having his own expected role functions, it follows that the behavior of each part . . . affects the functioning of the others. (p. 209)

Steinglass (7) proposed that alcoholism not only becomes enmeshed in family functioning but can also develop into an adaptive organizing mechanism for the family:

> Alcohol, by dint of its profound behavioral, cultural, societal, and physical consequences, might assume such a central position in the life of some families as to become an organizing principle for interactional life. . . . In such a system the presence or absence of alcohol becomes the single most important variable determining the interactional behavior. (p. 106)

According to the theoretical framework of our research, the family is powerfully motivated to maintain itself, even over generations. It strives to preserve the roles its members play, the values and beliefs they have in common, and the rules on which they agree. The family's shared perception of itself, or family identity, is conveyed by way of family rituals and myths.

Family rituals are patterns of behavior that have meaning beyond their practical outcome or functional purpose. Family myths are stories or legends that incorporate the crucial events, the important people, and the major themes of the family's history.

The underlying hypothesis of our research is that families which persist in maintaining their family rituals throughout the children's growing up period, even in the face of a serious parental alcohol problem, will evidence less transmission of alcoholism into the children's generation. Conversely, families whose rituals are substantially changed are much more likely to have alcohol problems in both generations. The former category of families we have called "distinctive," i.e.,

the alcohol abuse behavior remained distinct from the ritual life of the family. The latter group of families we have termed "subsumptive," indicating that the alcohol abuse behavior subsumed the ritual life of the family.

RESEARCH DESIGN

Our study group consisted of 25 families, primarily of middle- and upper-middle-class background and European origin, living in the greater Washington, D.C., area. All 25 families included at least 1 parent who met the criteria of Goodwin and associates for alcoholic or problem drinker (3). In 18 of the families it was the father who was the alcoholic; in 5, the mother; and in 2, both parents. Twelve families evidenced no alcohol problems in children's generation (nontransmitter); 7 families had at least 1 child who was a heavy drinker (intermediate transmitter); and 6 families included at least 1 child who was an alcoholic or problem drinker or who was married to a problem drinker (transmitter). According to our theoretical perspective, marriage to someone with an alcohol problem represents a perpetuation of the alcoholic family system and therefore constitutes transmission.

Chi-square tests verified independence between the transmission of alcohol problems and parents' ethnic background, religion, education, and occupation. T tests revealed no significant differences between families in the three transmission categories in respect to mean age of parents, length of time since alcoholic parent last drank heavily, and current drinking status of the alcoholic parent (active or inactive). The mean age of interviewed children in the transmitter families was higher than the mean age of interviewed children in the nontransmitter families, significant at the .05 level. However, no significant difference was found between the mean age of children with alcohol problems (26.9) and the mean age of children without alcohol problems (23.9).

Structured individual interviews were conducted with both parents in the 25 families and with as many grown children as were willing to participate in the study (N=63, an average of 2.5 children per family). The first interview covered the personal history of the interviewee, including an alcohol history and a history of his or her relationship with the family of origin and the present nuclear family. The second interview addressed the continuity of family heritage from the grandparents' generation into the current nuclear family and provided detailed information about 7 areas of family life while the children were growing up: dinnertime, holidays, evenings, weekends, vacations, visitors in the home, and discipline.

To avoid bias on the part of the research staff, a clinical psychologist who had no previous involvement with the study was employed to code the interview data. A coding manual was devised to direct the coder in this process, and all references to children's drinking habits were deleted from the interview transcripts.

Two issues were addressed in the coding for each family: 1) which family life areas were rituals and 2) what happened to those ritual areas during the period of the alcoholic parent's heaviest drinking. The coder was asked to answer 12 questions from the point of view of each family member interviewed in respect to the 7 areas of family life.

The first 5 questions assessed whether or not a given area of family life was characterized by patterned behavior and whether or not that area had ritual aspects. Patterned behavior is behavior that is repetitive, stable with respect to roles, and continued over time.

Our definition of ritual builds on the description of patterned behavior but also encompasses the elements of acceptance by family members of the continuation of this behavior in the same way time after time and symbolism, or attribution of meaning or purpose to the continuation of this behavior beyond any practical considerations.

The first 5 ritual-related questions focused on the family life before the period of heaviest drinking, and the last 7 alcohol-related questions referred to the time when the drinking was heaviest. We examined these two different periods to obtain a picture of the family and its rituals before the drinking was most severe and to determine what impact the alcohol-abusing behavior had on the family's already established rituals. In other words, we were looking for evidence of change in whatever rituals the family had developed.

Questions 6–12 addressed the following alcohol-related issues in respect to each area of family life: presence of the alcoholic parent, alcohol use by the alcoholic parent, intoxication of the alcoholic parent, response of the family to the intoxication, change in level of participation of the alcoholic parent when intoxicated, response of the family to that change, and overall change during the period of heaviest drinking.

We reduced the resulting codes in order to determine which areas of family life were rituals in each of the 25 families. Looking at those identified rituals, we determined the degree of change, if any, during the period of heaviest drinking. Each family was categorized as being distinctive (no overall change in the rituals), intermediate subsumptive (approximately half the rituals altered), and subsumptive (all rituals changed). Eight of the families were considered distinctive, 10 were considered intermediate subsumptive, and 7 were considered subsumptive. Table 1 shows the distribution of distinctive and subsumptive ritual life areas in each category.

To check interrater reliability, a staff member who had not previously worked with the data and had no information on the results was given 6 randomly selected family files to code. The original codes and the new codes were then compared for agreement on designation of each family life area within a family as patterned behavior and/or ritual (based on questions 1–5). For these 7 possible areas across the 6 families there was 88% agreement on the final decision of patterned

Intermediate subsumptive (N=10)	2	2	6
Distinctive (N=8)	0	3	5

[a] $p<.10$ by chi square when all three ritual change types are compared with all three alcoholism transmission categories.
[b] $p<.025$ by Fisher's exact test when only the extreme groupings of families (subsumptive and distinctive versus transmitter and nontransmitter) are considered.

behavior and 83% agreement on the decision of ritual. Reliability was also checked for the data obtained from alcohol-related questions 6–12. Comparison of the codes derived by summarizing across all identified ritual areas within each family yielded results of 67% agreement on questions 9 and 11; 83% agreement on questions 7, 8, and 10; and 100% agreement on questions 6 and 12. A second measurement for question 12, comparing final classification of families into ritual change types, resulted in an agreement score of 83%.

DATA ANALYSIS

To test our original hypothesis—the greater the change in family rituals, the more frequent the transmission of alcoholism to the children's generation—we examined the distribution of the 25 families studied according to transmission category and ritual change type. Table 2 displays that distribution. Using chi-square analysis, we arrived at results providing evidence for a relationship between change in ritual life and transmission when all 25 families were considered. All 6 transmitter families were in the subsumptive or intermediate subsumptive categories; the 7 intermediate transmitter families were evenly spread throughout the three ritual change types; and the 12 nontransmitter families clustered in the intermediate subsumptive and distinctive categories.

When we disregard all the intermediate categories for both transmission and ritual change and examine only the extreme groupings of families, we arrive at convincing results (see table 1), indicating that there is a relationship between substantial change in ritual life and transmission of problem drinking or alcoholism into the children's generation.

The coded data provided considerable additional alcohol-related information for the 25 families. This material allowed us to compare overall characteristics found in the three transmitter categories according to particular results from questions 6–12. Families without dinnertime or holiday rituals were excluded from this comparison. The 6 transmitter families were clearly more similar to each other than to either the intermediate transmitter or nontransmitter groups of families. At least two-thirds of the transmitter families conformed to the following characteristics: the alcoholic parent was usually present in the home during the time family rituals occurred, he or she was usually drinking at those times, he or she was usually intoxicated, the family accepted that intoxication by demonstrating no active or negative response, there was a change in the level of participation of the alcoholic parent, the family accepted that change in level of participation, and there was overall change in identified family rituals.

In comparison, at least two-thirds of the intermediate transmitter families shared only the following characteristics: the alcoholic parent was usually drinking, he or she was usually intoxicated, and the family accepted whatever change in level of participation occurred. At least two-thirds of the nontransmitter families, on the other hand, had only one outstanding quality in common: a rejection of the intoxication of the alcoholic parent through such means as confronting the alcoholic parent openly or privately or talking about his or her behavior disapprovingly.

When we specifically scrutinized change versus no change in dinner and holiday rituals for each family transmission category, we found that only the intermediate transmitter families had their dinnertimes altered and only the transmitter families had their holidays changed. Conversely, both the intermediate

transmitter and nontransmitter families kept their holiday rituals intact. This is noted because we have observed that holidays are ordinarily the family rituals most likely to persist, even in the face of a serious alcohol problem.

Certain answers to particular alcohol-related questions indicated protection of family rituals. For all families there were 5 possible protective characteristics: 1) that the alcoholic parent was not usually intoxicated, 2) that the family rejected the alcoholic parent's intoxication, 3) that there was no change in the alcoholic parent's level of participation in ritual areas, 4) that the family rejected any change in the alcoholic parent's level of participation in ritual areas, and 5) that there was no overall change in ritual areas during the alcoholic parent's period of heaviest drinking.

Taking into account all of the answers for all families in each transmission category, we found a relationship between percentage of protective characteristics and transmission category at below the .001 level of significance using chi-square analysis. As a group, nontransmitter families had the highest percentage of protective characteristics (53%); the transmitter families had the lowest (13%); and the intermediate transmitter families fell in the middle (34%).

DISCUSSION

In developing our concept of subsumptiveness we have attempted to describe a family-level process important in the transmission of alcoholism over generations of families. We found that some families maintained their ritual behaviors in spite of stress under the impact of alcoholism, while others were less able to maintain their rituals under similar stressful conditions. In the subsumptive families, alcoholism behavior had invaded normal family ritual behavior, thereby substantially changing family life. For these families, alcoholism became a central organizing force, ritual continuity was disrupted, and there was a higher risk of transmission.

In this research our objective was to distinguish these two family types. However, an examination of ritual change versus no change during the period of heaviest drinking demonstrated three distinct family styles of handling an alcohol problem. Therefore, our categorization of 25 families includes an intermediate grouping.

Distinctive Families

As a group, the 8 distinctive families had the following characteristics in common: whenever intoxication occurred at ritual times (a relatively rare event), the families tended to accept that behavior by ignoring it; there was very little change in the level of participation on the part of the alcoholic parent; and there was considerably less transmission of the alcoholism into the children's generation.

In general, the distinctive families appeared to be comparatively stable; the behavior of the alcoholic parent was relatively less intrusive. The quality of constancy of the distinctive families was due in part to the infrequency of intoxication relative to the intermediate subsumptive and subsumptive groups, the absence of an overt negative response by other family members when intoxication did occur, and the stability of participation of the alcoholic parent in family ritual life.

It is important to note that the characteristic of "no change in participation" can be interpreted in at least three ways: that the family insisted the alcoholic parent remain involved, even during the difficult times of his or her drinking, that the alcoholic parent was never very involved in family ritual life, or that family rituals occurred at intermittent intervals (i.e., holidays and vacations) rather than daily (i.e., dinner and evenings). In fact, our interview data indicated that in 4 of the 8 families the alcoholic parent (in these cases, always the father) had seldom participated in family ritual life before the period of heaviest drinking. Either due to isolation by other family members or self-imposed detachment, the alcoholic parent in these 4 families was never fully integrated into family rituals. Additionally, dinnertime—the most regular family ritual time—was not a ritual area for 3 of the distinctive families, indicating that in these families, at least, participation of the alcoholic parent did not occur on a daily basis.

There is evidence of considerable denial that an alcohol problem actually exists in some of these distinctive families, especially on the part of the children. Some of them stated in the interview that they never noticed any intoxicated behavior in their parents when they were growing up. Perhaps such denial is another means for the family to keep alcoholism distinct from family rituals. Whatever the strategy used by each of these families, the result is that there was significantly less transmission in the children's generation.

Intermediate Subsumptive Families

Although the overall categorization of the intermediate subsumptive group as intermediate was based on moderate change in family rituals, additional information about each of these 10 families indicates that their approach to the alcohol problem was clearly different from that of families in the other two groups. In the intermediate subsumptive families the alcoholic parent was usually present during ritual times, he or she was usually drinking, he or she was usually intoxicated, the family tended to reject that intoxicated behavior, the alcoholic parent participated less in ritual life, the family tended to reject that diminished participation, and there was less transmission of alcoholism than in the subsumptive families but more than in the distinctive families.

Our overall impression of these families was that much more activity occurred around the alcohol abuse behavior than in the distinctive families. They seemed to be families in flux, families that responded overtly to the alcohol abuse behavior and change in level of participation in such a way that the family's response

may have contributed to the moderate alteration of family ritual life. Ritual change might have been caused by the family's active struggle with the alcohol problem. Typically, there was less denial of the alcohol problem in intermediate subsumptive families than in distinctive families and less transmission than in subsumptive families.

Subsumptive Families

In direct contrast to the distinctive families, the ongoing ritual behavior in the 7 subsumptive families was invaded by the alcohol abuse behavior; it changed the fabric of family life. As a group the subsumptive families had the following characteristics in common: alcohol use by the alcoholic parent usually occurred, intoxication usually occurred, the alcoholic parent participated less in ritual life, family members tended to accept that change in level of participation, and the greatest transmission occurred.

These families exhibited a highly disrupted family life, and they were clearly the most vulnerable to the effects of the alcohol problem. In comparison with the other two groupings, the subsumptive families were less stable, as evidenced by the fact that all identified family rituals were altered during the period of heaviest drinking. As in the distinctive families but unlike the intermediate subsumptive families, subsumptive families had their ritual life concentrated at such intermittent intervals as holidays. Three of these families had no dinnertime rituals, perhaps indicating a deterioration of daily rituals in advance of the time the alcohol problem became most serious. Among the subsumptive families there was a far greater frequency of alcohol use and intoxication by the alcoholic parent at ritual times, with much less rejection of that behavior by other family members than in the intermediate subsumptive families. In their acceptance of less participation by the alcoholic parent at ritual times, these families might have been demonstrating their great relief at the decreased involvement of the alcoholic parent, who frequently wreaked havoc in ritual life, embarrassing other family members and making them anxious about future ritual activities. The decreased involvement of the alcoholic parent was often the most acceptable solution for these families. In short, the subsumptive families were incapable of keeping the impact of the alcohol problem under control.

We have found that there was a relationship between the maintenance or disruption of family rituals and the recurrence or nonrecurrence of alcoholism over generations in our 25 families. Furthermore, we have found that the degree of ritual change in family life was an overall reflection of specific family styles of handling a serious alcohol problem.

Short-Term Spatial Memory Deficits in Men Arrested for Driving While Intoxicated

BY ERIC W. FINE, M.D., AND ROBERT A. STEER, ED.D.

In the light of the fact that ethyl alcohol can cause damage to the brain, especially in the area of motor control, a study of the incidence of alcohol-related neuropsychological impairment in individuals arrested for driving while intoxicated (DWI) would be of great value. The authors report on 100 DWI offenders given a Memory-for-Designs Test: 33% of the offenders were in the borderline range for organicity and a further 24% were in the critical range. Although they advise caution in interpreting these data, the authors point out a number of implications their analyses have for those interested in alcohol-related highway safety programs.

THE FACT THAT ethyl alcohol can cause damage to the brain is now widely accepted. However, there is a surprising lack of awareness as to how common alcoholic brain disorders really are, although Lemere (1) observed more than 20 years ago that "for each alcoholic with demonstrable pathology, there must be thousands in intermediate stages of danger." Since the 1960s, psychological studies of alcoholics have been accumulating in the scientific literature suggesting that alcohol produces neuropsychological impairment. In an excellent review of this literature, Tartar (2) concluded that "there is substantiative experimental evidence of a psychological nature to implicate a neurological impairment in chronic alcoholics."

Using the Halstead-Reitan Battery, several investigators (3, 4) have found that there is a neuropsychological impairment in alcoholics but that it is not as severe as that found in patients with traumatic brain injury. Tartar (5, 6) compared alcoholics, people with brain injuries, and experimentally lesioned animals and found many similarities among these groups. Among other impairments was a "marked inability of alcoholics to temporally organize behavior and persist with a cognitive act."

Received Sept. 1, 1977; revised Jan. 12, 1978; accepted March 14, 1978.

It appears likely that alcoholic patients do not manifest global neuropsychological impairment but demonstrate particular deficits on tasks requiring visual-spatial information processing (7). There is also evidence suggesting that the duration of alcohol abuse is correlated positively with a progressive decline in competency (8–10). It is possible that the psychological deficits observed in alcoholics are influenced by the nutritional status of the subjects: thiamine deficiency is a well-known complication of chronic alcoholism. However, there is experimental evidence from animal studies (11, 12) indicating that alcohol has a deleterious effect on learning and timing behavior in spite of adequate nutritional status. Clarke and Haughton (13) found significant intellectual impairment among a group of heavy drinkers; they also found that these heavy drinkers remained impaired for a considerable time after drinking had been discontinued.

The most obvious effects of alcohol are on motor control. Deficient performances by alcoholics compared with normal subjects have been found in tests of finger tapping (14), finger and manual dexterity (15), and muscle strength (10). These disturbances are thought to be most likely cerebellar in origin.

It would obviously be of value to determine the incidence of alcohol-related, neuropsychological impairment in a group of people arrested for driving while intoxicated (DWI), but we found no such studies in the literature. Many investigators (16, 17) have confirmed the presence of heavy, prolonged alcohol intake in a substantial proportion of DWI offenders. Fine and Scoles (18) noted that about 64% of a group of DWI offenders were alcohol-dependent and were therefore likely candidates for early case-finding and secondary prevention of alcoholism. The average blood alcohol concentration (BAC) of these offenders at the time of arrest was .18%, and the subjects described themselves as having maintained the same drinking pattern for an average of 9.58 years. Given these degrees of involvement with alcohol, it is important to ascertain whether or not DWI offenders show any signs of organic brain syndromes.

METHOD

Study Group

The subjects for this study were 100 men admitted to the Alcohol Highway Safety Diagnostic Unit of the

0002-953X/79/05/0594/04/$00.45 © 1979 American Psychiatric Association

West Philadelphia Community Mental Health Consortium. The 100 men represented consecutive admissions referred for diagnostic appraisal as part of the city of Philadelphia's Alcohol Highway Safety Program over a period of 2 weeks. The referrals were made by the court, which used diagnostic assessments to determine whether or not the men should be sent to educational safe-driving classes or to the appropriate alcoholism treatment.

The sample was composed of 41 white men and 59 black men. Their mean age was 40.82±11.22 years, and their mean educational attainment was 9.69±3.53 years. The marital status of the men was complex: 17% had never married, 54% were currently married, 16% were separated, 10% were divorced, and 3% were widowed.

Only 9 of the men had been treated for alcoholism, but 31 had been arrested for driving while intoxicated before. The mean length of their current drinking pattern was 10.47±8.94 years. The mean breathalyzer score, furnished by the Philadelphia Police Department and obtained at the time of arrest, was .18%±.05%. The National Institute on Alcohol Abuse and Alcoholism's Quantity-Frequency (QF) Index (19), which represents the average number of ounces of alcohol intake per day over the past month, was calculated for the men; their mean QF Index score was 1.33±2.70 oz. We also used another measure of alcohol impairment developed for NIAAA, the Impairment Index (19), which is composed of 12 questions asking about the extent of self-perceived problems attributed to excessive alcohol use over the past month. The mean Impairment Index score was 3.93±5.00. The QF Index and Impairment Index scores were higher than those reported for drinking American adults (.8 oz. and 1.2, respectively).

Instrument

The instrument used to measure short-term spatial memory deficits was Graham and Kendall's Memory for Designs Test (MFD) (20). The MFD has been used in a number of diverse clinical investigations and has been found useful for assessing mild organic complications. Briefly, the test consists of 15 designs, each printed in black on a 5-inch cardboard square. Each of the designs is shown to the subject for 5 seconds. After the 5-second exposure, the design is withdrawn and the subject is asked to draw one exactly like it. It takes about 10 minutes to complete the entire test.

Higher total scores are associated with poorer performance. The scoring of each design is based on the following criteria: a score of zero reflects a satisfactory reproduction, an omitted figure, or incomplete reproduction; a score of 1 represents a drawing in which there were two easily identifiable errors but the overall design was adequate; a score of 2 indicates more than two easily identifiable errors; and a score of 3 indicates that a drawing has been reversed or rotated.

The MFD was administered to the 100 subjects by the clinicians who were conducting the diagnostic interviews. These clinicians were trained in the administration of the test by one of us (R.A.S.), who later scored all 100 tests. The MFD was presented at the end of the diagnostic interview, which lasted approximately an hour. None of the men was judged to be intoxicated by the interviewers, nor did any of the men admit to drinking just before the interview. The MFD drawings were given to the scorer without any information about background or drinking histories.

[b]$p < .01$.
[c]$p < .05$.

RESULTS

The mean MFD score for the 100 DWI offenders was 8.15±8.33; this mean is within the borderline range reported by Graham and Kendall (20). Diagnostically, 43% of the subjects were within the normal range (score of 0–4), 33% were within the borderline range (score of 5–11), and 24% were within the critical range (score of 12 or more). These percents differ from those given for control subjects in the MFD manual (20): 79% of the matched validation control group were normal, 17% were borderline, and 4% were critical. However, that control group represented a wide disparity in age. Focusing on the 22 control subjects whose ages were between 41 and 45 (the range in which the mean age of the present sample fell), the

average score was 4.00; the control group's mean score was thus approximately half that of the present sample.

To ascertain whether or not the men's background characteristics and drinking behaviors were related to their MFD total scores, nine background characteristics and drinking behaviors were correlated with the MFD scores (see table 1). Only previous arrest for driving while intoxicated and the QF Index were not significantly related to the MFD scores.

Since the background characteristics and drinking behaviors were intercorrelated, we decided to enter all of the variables into a stepwise regression analysis for the MFD scores. Table 2 presents the stepwise regression for the MFD scores. Education, age, and the Impairment Index contributed significant amounts of variance to the explanation of the MFD scores. The Impairment Index was significantly related to the MFD scores ($p<.05$), even after the influences of education and age were controlled for.

DISCUSSION

The findings reported here must be interpreted with caution: 33% of the men in this sample were within the borderline range for organicity, and a further 24% were in the critical range. Such results give great cause for concern because MFD performance has been shown significantly to differentiate subjects with brain disorders from those without brain disorder (20). The fact that the present results were found in individuals referred for evaluation after being arrested for driving while intoxicated suggests that the clinical and judicial management of such individuals requires serious reconsideration.

The relationships of the MFD scores to age, education, and the Impairment Index indicate that older, less educated men with higher levels of impairment due to alcohol had the most difficulty in remembering the spatial designs. When age and education were controlled for in the stepwise regression, there was still a positive relationship between the MFD scores and the Impairment Index. This finding might indicate an association between alcoholic symptoms and possible organicity.

Great emphasis has been given to the types of alcohol abuse and dependency in DWI offenders, and there has been considerable debate in the literature concerning the role of psychological factors in drinking drivers (21, 22). This study highlights another important variable that must be considered by people interested in alcohol highway safety programs.

In their study of alcoholic intellectual impairment Clarke and Haughton (13) found that heavy drinkers exhibited deficits in perceptual-motor coordination and abstract reasoning that would pose driving difficulties, especially in situations demanding sudden reactions and quick decisions. The findings of the present study suggest that some DWI offenders also display short-term spatial memory deficits; these drivers might not be able to remember road signs, traffic alerts, or emergency signals. This finding becomes particularly alarming when one realizes that the current sample was not drawn from chronic alcoholic patients but from people arrested for routine alcohol-related traffic violations. It is important to emphasize that these results were obtained when the subjects were clinically judged to be free of alcohol; they would be expected to be more impaired after alcohol consumption.

The results of this research might have been affected by the degree to which the subjects were under the influence of alcohol at the time of testing and by their high levels of anxiety (they were interviewed after having been arrested). We attempted to minimize these factors by excluding from the study anyone who admitted to drinking on the day of the interview or who showed any alcohol-related symptoms. The diagnostic interviews, including the MFD, were conducted by highly trained and very experienced personnel who worked exclusively with DWI offenders. The MFD was administered at the end of an hour-long interview, during which time any alcohol-induced interference with performance would have become apparent. Our experience has been that patients are much less anxious following the interview, which is conducted in a nonthreatening empathic fashion. Future investigators might well consider the use of a breathalyzer to ensure that the subjects' BAC is zero when they take the MFD.

One other possible source of bias should be mentioned. Although the person scoring the MFD had no knowledge of the drinking history of the subjects, he obviously knew they had all been arrested for driving while intoxicated. Therefore, we did not have the advantage of a truly blind evaluation.

The possibility of short-term memory impairment in DWI offenders has implications for the type of programs offered to them by the judicial and mental health systems. In general, these programs usually offer combinations of sanctions, education, and, occasionally, treatment. If there is a high incidence of organic brain damage in DWI offenders, each of these approaches will require modification. For example, depending on the extent of impairment, the courts might be obligated to impose long-term suspension of the driver's license with the option of reinstatement after appropriate medical and psychological review. Driver education courses for these offenders might have to be extended to allow for the repetition of content. Individual assessments of potential learning disabilities should also be included in these courses. If there is a suspicion of organicity during the course of psychological assessment, a neuropsychiatric evaluation should be performed. On the basis of the findings of this latter evaluation, a comprehensive treatment regimen should be prescribed. The regimen might include mandatory abstention from alcohol, appropriate medication, and highly structured, direct psychotherapy.

Further investigations of the validity and reliability of the short-term spatial memory deficits found here should be undertaken. The MFD must be regarded as a screening instrument only; it cannot substitute for a thorough neuropsychological testing procedure such as the Halstead-Reitan Battery. Ideally, DWI offenders suspected of having organic brain damage should be referred for neurological evaluation and for such possible specialized investigations as computerized axial tomography.

Computerized Transaxial Tomographic and Neuropsychological Evaluations in Chronic Alcoholics and Heroin Abusers

BY SHIRLEY Y. HILL, PH.D., AND MICHAEL A. MIKHAEL, M.D.

Computerized transaxial tomographic (CTT) scans and the Halstead-Reitan Neuropsychological Battery were administered to 42 paid male volunteers (15 chronic alcoholics, 15 heroin abusers, and 12 matched control subjects). CTT scans revealed that only 1 of the chronic alcoholics had a ventricle/brain (V/B) index larger than normal. One unexpected finding was that the heroin abusers had significantly smaller sulci and V/B indices. Neuropsychological assessments of the alcoholics and heroin abusers revealed functional impairment in a majority of cases; the alcoholics were twice as likely as opiate abusers to show impairment.

CHRONIC ALCOHOLISM and heroin abuse may affect as many as one in five urban men (1, 2). The relationship between the abuse of psychoactive drugs and brain damage has been widely debated as substance abuse continues to be a persistent social and medical problem. A number of studies have assessed brain damage using a variety of psychological tests (3–6); others have used pneumoencephalography (7, 8), the EEG (9, 10) and, more recently, computerized transaxial tomography (CTT) (11–13).

Unfortunately, few studies have used the proper controls necessary to conclude that an association exists. Most studies involving psychological tests have ignored demographic variables that can alter the proportion of individuals diagnosed as impaired (14). In addition, the focus of previous studies concerned with the effects of opiate abuse has been restricted to polydrug abusers because of the great difficulty in finding individuals who have only abused opiates. Polydrug abuse may also complicate the study of alcoholism and its association with cerebral impairment. Only by eliminating polydrug abusers from studies of this type can the relative risk associated with the chronic abuse of particular drugs be determined.

Further, in the few studies completed to date that have utilized CTT, subject selection has been based on persistent abnormal functioning, neurological signs, or other indicators warranting CTT scans (11, 12). Clearly, data have previously not been available to determine the rate of cerebral atrophy in a randomly selected population of substance abusers.

The purpose of the present study was to determine whether alcoholics and heroin abusers exhibit comparable neuropsychological impairment as assessed by the Halstead-Reitan Neuropsychological Battery and whether structural alterations are manifest using CTT scans.

METHOD

Subjects

Forty-two male subjects were selected for neuropsychological testing and CTT. These subjects were alcoholics (N=15), heroin abusers (N=15), and controls who had never abused drugs (N=12). The subjects were part of a larger study of neuropsychological impairment in approximately 100 substance abusers. The alcoholics and heroin abusers having the least amount of multiple drug abuse were chosen from this larger pool of subjects for CTT study. Each had been given an extensive psychiatric interview covering lifetime history of substance abuse. The interviews ensured that subjects in the alcoholic group had never abused opiates and that none in the opiate group had ever abused alcohol. Similarly, the control group consisted of individuals who had never abused alcohol, opiates, barbiturates, stimulants, or hallucinogens.

The extensive drug history interviews also allowed for control for any possible acute effects of drugs on neuropsychological tests. It was determined that 8 of the alcoholics and 6 of the heroin abusers had been in remission for 1 month or more; 4 of the 8 alcoholics had not drunk for at least 6 months, and 3 of the heroin abusers had not used heroin for at least 6 months.

Subjects were drawn from outpatient alcoholism and drug abuse programs in the St. Louis, Mo., area (i.e., Malcolm Bliss Mental Health Center, Veterans Administration Hospital, Narcotics Service Council). Persons included in the study had a minimum education of 10th grade, were at least 25 years old, and had no history of head trauma or high fever. The control group was drawn from churches and social groups in the St. Louis metropolitan area.

Because demographic variables may influence psychological test scores, the groups were matched as closely as possible for age, education, race, and socioeconomic status. The mean ages of the alcoholics, opiate abusers, and controls were 34.3, 29.2, and 28.0 years, respectively. Their respective educational levels were 11.0, 11.5, and 12.7 years of school. Most of the subjects were black, with only 3 of the alcoholics being white. The subjects were asked about the best job they had ever held; this occupation was coded using a socioeconomic index classification (15). The three groups were well matched for socioeconomic characteristics. The alcoholics had a socioeconomic index of 14.5, the heroin abusers 23.6, and the controls 28.1. These values correspond approximately to semiskilled to skilled labor.

All of the subjects in the alcoholic group met a diagnosis of alcoholism by the criteria of Feighner and associates (16). This diagnosis was based on criteria including physical dependence, social and legal problems resulting from alcohol abuse, and the person's own estimation that he drank too much. In addition, all of the subjects selected for study reported drinking a fifth of liquor per day when they were drinking. The average length of time they had drunk heavily was 14.3 years, with a range of 7–25 years.

The group of alcoholics chosen for study was characterized by an absence of opiate or other drug abuse. Nine of the 15 alcoholics had never used barbiturates, stimulants, or hallucinogens. The remaining 6 had never used these drugs on a regular basis (3 or more times per week). Six of the alcoholics had never tried marijuana, 6 had used marijuana infrequently (less than once a week), and 3 had used it as often as once or twice a week.

All of the subjects in the heroin abuse group met a diagnosis of drug abuse by the criteria of Feighner and associates (16) and had taken opiates three or more times a week for a minimum of 4 years. The group as a whole had abused opiates an average of 8.6 years; the longest use was 14 years. The available street drugs in St. Louis included heroin, morphine, codeine, hydromorphone (Dilaudid), and meperidine (Demerol). Nine of the 15 subjects had used methadone for more than a year, and 5 had used it for at least 4 years.

The attempt to select opiate abusers with minimal use of other drugs was largely successful. Although all but 1 subject drank alcohol socially, only 4 could be characterized as regular drinkers (7 or more drinks at one time at least once a week). All used marijuana; 8 used it one or more times a week, while 7 used it infrequently (less than once a week). All had tried stimulants, but more than half had used them less than 25 times in their life, with only 3 using them regularly (3 or more times per week). Two-thirds of the group had used barbiturates at some time in their life but never on a regular basis. These 10 subjects had a lifetime use averaging only 27 times. The remaining 5 subjects reported never having used barbiturates. LSD use was uncommon; 1 subject had used it twice, and 3 had used it once.

Twelve control subjects were chosen whose demographic characteristics matched as closely as possible the characteristics of the alcoholic and opiate abuser groups. These 12 subjects were selected from a population of 60 volunteers because they had no history of drug abuse. All but 1 of them drank alcohol socially, but none was a heavy user of alcohol. One control subject had experimented with barbiturates (15 times), while 4 had tried stimulants (all less than 10 times). One of the controls had inhaled heroin once, and 4 had used psychedelic drugs (none more than 3 times). All had tried marijuana, but none had ever smoked it more than 4 times a week.

CTT Scans

CTT scans were performed using the standard technique. A total of eight images were obtained based on four scanning sequences. Polaroid images were used to determine the first lower cut showing the lateral ventricles. Four consecutive slices were then used to measure the size of the lateral ventricles and the brain.

Evaluation of the CTT scans consisted of measuring the area of the lateral ventricles and the area outlined by tracing the inner table of the skull in each of the four slices under consideration. In those cases in which the ventricles were entirely included in three slices, the value of the ventricular area in the fourth slice was considered to be equal to zero. The sum of the areas of the ventricles in four slices was divided by the sum of the areas of the cranium, and the ratio was expressed as a percentage or ventricle/brain (V/B) index.

This method is a modification of that used by Synek and associates (17). However, measurements taken directly from Polaroid pictures have a minification factor of about 3.6. In addition, slight errors in the measurement on a minified image lead to larger errors in computed values. Therefore, the ventricular area was determined by tracing the perimeters of the lateral ventricles and the inner table of the skull using a transparency superimposed on the numerical computer printout. A hand planimeter, moved around the perimeters of the lateral ventricles and cranium that had been traced, allowed measurement of each slice. All measurements were completed twice. Using this technique, the areas of the ventricles rather than the linear distance across the ventricles could be determined (18).

The width of the sulci was judged blindly by two independent raters using the following numerical

classification: 1=small or absent, 2=middle range, and 3=large. Although all of the sulci would ordinarily be considered within the normal range, obvious gradations were observed among the 42 subjects.

RESULTS

Neuropsychological Functioning

Results of the neuropsychological tests were analyzed in two ways. Duncan's multiple range test was used to compare the heroin abusers and controls and the alcoholics and controls. The number of individuals whose scores fell in the impairment range was evaluated according to established norms.

The Shipley-Institute of Living Scale for Measuring Intellectual Impairment and the Peabody Picture Vocabulary Test were used to ensure that the groups were equated for overall intelligence. No significant difference was found for the Shipley or the Peabody test, indicating that overall intelligence was equated across groups. All comparisons between the alcoholic and control subjects on tests of neuropsychological functioning were significant, as were all but two of the comparisons between the heroin abusers and the controls (see table 1). An important point is that unlike the alcoholic subjects, the opiate abusers performed as well as the controls on the Category Test, which measures abstract reasoning ability. Deficits in abstract reasoning are an especially prominent feature of impairment in chronic alcoholics. Results of a number of studies using the Category Test with chronic alcoholics have shown a remarkable consistency in the frequency of reported impairment (5, 19, 20). Significant neuropsychological impairment was noted for the alcoholics and heroin abusers (table 2), with 75% of the alcoholics and 37.5% of the heroin abusers exceeding the normal range for the Average Impairment Index. A cutoff score suggested by Russell and associates (21) was used to assess overall impairment.

A second set of norms was used to determine the proportion of subjects who fell outside the normal range. Cutoff scores developed in Oklahoma by Vega and Parsons (22), which have been found to discriminate brain-damaged from non-brain-damaged individuals quite well, were applied to the test results. According to these cutoff scores, twice as many alcoholics as heroin abusers once again showed overall impairment. Among the alcoholics, 40% had an Average Impairment Index exceeding the normal range, whereas 20% of the heroin abusers were similarly affected. None of the controls showed overall impairment.

CTT Scans

Statistical analyses of the V/B indices obtained for the three groups indicated that on the whole the alcoholics were not significantly different from the controls, and the opiate abusers were not significantly different from the controls. However, a comparison made between the alcoholics and the heroin abusers indicated a significant trend ($\chi^2=3.40$, df=2, $p<.10$), which was probably due to the large percentage of heroin abusers with small V/B indices (table 3). In a previous study (13) 34 control subjects without a drug history were found to have V/B indices less than 6.0. On-

TABLE 3
Distribution of V/B Index for Alcoholic Subjects, Heroin Abusers, and Controls

	V/B Index					
	<2.4		2.4–4.5		4.6+	
Group	N	%	N	%	N	%
Alcoholics	6	40.0	7	46.7	2	13.3
Heroin abusers	11	73.3[a]	3	20.0	1	6.7
Controls	7	58.3	4	33.3	1	8.3

[a]Significant trend compared with the alcoholics (χ^2=3.40, df=2, p<.10).

TABLE 4
Distribution of Sulci Size for Alcoholic Subjects, Heroin Abusers, and Controls

	Size of Sulci[a]		
Group	1	2	3
Alcoholics[b]	0	8	7
Heroin abusers[c]	4	11	0
Controls	0	9	3

[a]1=small or absent, 2=middle range, 3=large.
[b]There was no significant difference between the alcoholics and controls in size of the sulci (χ^2=1.34, df=2).
[c]The sulci of the heroin abusers were significantly smaller than those of the alcholics (χ^2=11.47, df=2, p<.001) and the controls (χ^2=6.95, df=2, p<.01).

ly 2 of the subjects in the present study exceeded this value—1 alcoholic with a V/B index of 7.60 and 1 heroin abuser with a V/B index of 8.70.

Since a disproportionate number of cases among the opiate abusers had a V/B ratio less than 2.4, it is particularly noteworthy that significantly more of the opiate abusers fell in the group characterized by small or absent sulci, as seen in table 4. The cerebral sulci of the opiate abusers were significantly smaller than those of both the controls (χ^2=6.95, df=2, p<.01) and the alcoholics (χ^2=11.47, df=2, p<.001). These findings suggest that opiates produce specific effects distinct from those seen with cerebral atrophy (enlarged ventricles and sulci).

DISCUSSION

Two recent CTT studies have demonstrated neuroanatomical changes in alcoholics without chronic brain syndrome. Ventricular enlargement was noted in 67% of the alcoholic patients in one study (11), and there was evidence of cerebral atrophy in 58% of the patients in another study (12). However, these studies cannot be taken as estimates of risk for cortical atrophy or intellectual impairment among alcoholics on the whole. Strict selection criteria were not used in these studies; CTT scans were obtained because the patients had displayed clinical criteria warranting further neurological consideration. Additional difficulties with previous CTT studies are the lack of age- and sex-matched control groups and the fact that measurements of the ventricles were linear. For these reasons, previous studies may have overestimated the degree of atrophy actually present among alcoholics. Further, these high rates for alcoholics are in direct contrast to our findings. Based on a V/B index of 10 as indicative of clear atrophy (17), none of our 30 alcoholics and heroin abusers showed atrophy, although 1 alcoholic and 1 control subject exceeded a score of 6.0.

Although patients with chronic brain syndrome or Korsakoff's syndrome exhibit the most striking intellectual impairment, many more alcoholics may suffer from subclinical forms of brain damage. It has been reported in many investigations that alcoholics have normal IQs and intact verbal capabilities, with deficits in abstracting ability as measured by the Category Test (5, 19, 20). The present results are in agreement with these previous findings concerning impairment in alcoholics on the Category Test.

Neuropsychological deficits in association with opiate abuse have previously not been tested in subjects without a history of abuse of other drugs, although polydrug abusers have been reported to be neuropsychologically impaired. Adams and associates (23), studying polydrug abusers of whom about one-third had abused opiates, found deficits on a number of tests, including the Category Test, Tactual Performance Test, and the Tapping Test. In another study, by Grant and Judd (24), 45% of the 66 polydrug abusers examined had impaired neuropsychological functioning as measured by the Halstead-Reitan battery. About one-third of these polydrug abusers had abused heroin, and one-fourth had abused alcohol. It was not possible in these studies to determine the importance of alcohol or opiate abuse alone.

The present investigation of individuals who were almost exclusively abusers of opiates demonstrated that significant neuropsychological impairment may occur as a result of abuse of this class of drugs. Unlike the alcoholics, who frequently exhibited marked impairment on the Category Test, the heroin abusers in the present study did not show this deficit as often or with as large a deviation from controls. Since impairment on this test is thought to correlate with frontal lobe damage or right hemisphere involvement (25), one may speculate that these areas are less vulnerable to the opiates. In other respects, the neuropsychological impairment seen in the opiate abusers was similar to that seen in the alcoholics, i.e., impaired performance on the Tactual Performance Test (Memory and Location) and the Tapping Test. However, overall impairment on these tests (Average Impairment Index) was present in twice as many alcoholics as opiate abusers. Further, using our criteria for probable cerebral atrophy as evidenced by CTT scans, as many alcoholics as opiate abusers showed a tendency toward enlarged ventricles. However, the number of individuals so affected was quite small.

One unexpected CTT finding that may be particularly noteworthy was the statistically significant number of heroin abusers who had very small or visually absent sulci. We can only speculate as to the possible

mechanism that could account for this difference. A number of reports (26–28) have indicated that antigenic sensitization to narcotics or accompanying adulterants may occur. Opiates are not antigenically inert. Morphine, codeine, meperidine, and opium are capable of producing acute allergic responses. Urticaria, angioneurotic edema, acute transverse myelitis, and anaphylactic shock have been reported to occur, presumably as a result of the capacity of opiates to release histamine (29). An allergic phenomenon has also been implicated in acute myoglobinuria seen in association with heroin addiction (30). Acute myoglobinuria is characterized by generalized muscle tenderness and edema. If chronic edema of the brain were a possible extension of these phenomena, resulting in chronic swelling, then the small V/B indices and small or absent sulci observed among the present group of heroin abusers might be a logical prediction. In any case, this finding appears to be worthy of further study.

Craving for Alcohol in Sober Alcoholics

BY ROY J. MATHEW, M.D., D.P.M., M.R.C.PSYCH, JAMES L. CLAGHORN, M.D., AND JOHN LARGEN, M.A.

The craving for alcohol experienced by 46 abstinent alcoholics was investigated with a structured interview, a personality inventory (the neuroticism Scale Questionnaire), and a mood state adjective checklist (Profile of Mood States). It was found that craving is a continuum, not an all-or-none phenomenon. The intensity of craving was positively correlated with the trait anxiety of the subject and inversely correlated with the duration of abstinence from alcohol. A large proportion of the craving was precipitated by environmental factors and relieved by psychological methods. A variety of mood changes accompanied craving. Only one mood state, anger-hostility, significantly differentiated subjects who experienced mild craving from those reporting severe craving.

"CRAVING" is used in this paper to denote an overpowering desire to drink alcoholic beverages (1). A sizable percentage of alcoholics experience craving before consuming alcohol, but systematic studies regarding this phenomenon are few.

Mello (2) questioned the very existence of the phenomenon of craving. However, Hore (3), in a mail questionnaire study of alcoholics in the United Kingdom, found that 33% of the respondents had definitely experienced craving in the last 7 days. Flaherty and associates (4) showed that periods of craving occurred frequently during the first year of sobriety.

Several investigators have hypothesized the existence of two types of craving: a psychological need to consume alcohol, which is often present before the onset of alcoholism, and a need to consume alcohol to relieve withdrawal symptoms (5). According to Ludwig and associates (6), the withdrawal syndrome and the craving are conditioned responses to a number of introceptive and extroceptive stimuli. Withdrawal symptoms and associated craving that occur as late as two months after termination of drinking have also been described (7). Since the diagnosis of alcohol withdrawal is made on a purely symptomatic basis, its differentiation from anxiety can be complicated. It is difficult to distinguish whether the anxiety experienced with craving is a delayed withdrawal syndrome or anxiety neurosis. It is equally difficult to decide whether the anxiety is primary or secondary to the craving experience. Other mood states also have been associated with craving. Hore (3) found that craving occurred under various circumstances, including social and drinking situations and altered mood states. Sixty-nine percent of his subjects described craving in terms of physical symptoms, 40.8% in terms of mental symptoms, and others claimed miscellaneous symptoms. In the Flaherty and associates study (4), craving spells corresponded with deep depressions and late withdrawal symptoms.

The association between alcoholism and affective disorders was investigated by Winokur and associates (8–11), who reported a possible underlying affective change in craving. Craving has also been studied under carefully controlled laboratory conditions using stimulation and simulation techniques. On the whole, these experiments demonstrated that craving is not always associated with drinking behavior. The majority of these studies investigated the craving experience that followed the first drink rather than the craving that preceded the drinking (2). It is debatable whether such data support the existence of the phenomenon of craving (12).

The present investigation was conducted to study the characteristics of craving and the factors that influence its appearance and disappearance.

METHOD

The subjects, 34 men and 12 women residents of three hostels for recovered alcoholics, were interviewed after the study was explained fully and they gave informed consent to participate. Only subjects given a "definite diagnosis of alcoholism," using the criteria described by Woodruff and associates (13, pp. 205–206) were included in the study. Craving was defined as the desire to drink alcohol before the consumption of the first drink. Assessments were obtained for each subject during a structured interview

with a psychiatrist. A questionnaire on craving and an alcoholism questionnaire were constructed in order to systematically record information regarding the nature of craving, the duration of drinking patterns, complications of alcoholism, demographic information, etc.

Subjects were asked to complete the Neuroticism Scale Questionnaire (NSQ) and the Profile of Mood States (POMS). They were instructed to fill out the POMS according to the mood and feelings experienced during the most recent craving episode. Data for each participant were collected once.

The NSQ is a brief self-report inventory that measures the degree of an individual's neuroticism. In addition to a total neuroticism score, the 40-item test provides measures of tendermindedness, depression, submissiveness, and anxiety. The POMS is a 65-question self-report inventory that measures six clearly defined dimensions of mood: tension-anxiety, depression-dejection, anger-hostility, vigor-activity, fatigue-inertia, and confusion-bewilderment.

RESULTS

Subject Characteristics

Frequency tallies were calculated for each of the items on the alcoholism and craving questionnaires, and characteristics of the subjects emerged as follows: of the 46 subjects interviewed, 34 (74%) were male and 12 (26%) were female. Twenty-nine of the 46 subjects (63%) were separated or divorced, 11 (24%) were single, and 4 (9%) were married.

The mean age of the group was 37.8 years (SD=10.5). The alcoholism questionnaire indicated that the mean age of alcoholism onset was 25.9 years (SD=9.7), followed by a mean duration of alcoholism of 12.2 years (SD=8.7). The mean period of current abstinence from alcohol was 6.0 weeks (SD=5.3).

Precipitating Factors and Severity of Craving

The craving questionnaire was designed to indicate the various external factors that may precipitate the craving for alcohol.

Table 1 represents a subset of the craving questionnaire and gives the frequencies of subjects responding positively to each question. As the table indicates, craving appeared to be induced by a variety of factors, particularly unpleasant ones. It should be noted that the categories in table 1 are not mutually exclusive and that 15 subjects answered "yes" to both of the first two items and 11 answered "yes" to the first three questions.

The craving questionnaire included a series of items constructed to test our hypothesis that craving can be seen as a continuum (see table 2).

Response frequencies did not occur in a bimodal pattern, the expected distribution if craving were an all-or-none phenomenon. Instead, craving seemed to range from "none" to an intense presence so pervasive that drinking inevitably ensued. Thus it appears that craving can be conceptualized as a continuum.

TABLE 1
Responses to Questions Regarding Precipitating Factors

Precipitant	N	%
External events related to alcohol drinking	19	48
External non-alcohol-related events of an unpleasant nature	34	85
External non-alcohol-related events of a pleasant nature	23	58
Depression unrelated to external events	7	18
Elation unrelated to external events	4	10

TABLE 2
Frequency of Positive Responses to Questions on Severity of Craving

Severity	N	%
Never experienced craving (noncraver)	6	14
Recognized craving spontaneously but can ignore it (mild craver)	14	32
Recognized craving spontaneously but can keep it under control with great effort (moderate craver)	16	36
Craving invariably leads to drinking (severe craver)	8	18

TABLE 3
T Score Means for Profile of Mood States[a]

POMS Dimensions	Mild Cravers (N=14)	Moderate Cravers (N=16)	Severe Cravers (N=8)
Tension-anxiety	50.7	54.9	57.3
Confusion-bewilderment	51.7	51.1	55.6
Depression-dejection	56.1	55.6	61.4
Fatique-inertia	53.5	49.7	52.1
Vigor-activity	49.6	48.1	57.4
Anger-hostility	57.3	50.9	61.6

[a]The POMS was not given to the noncravers.

Duration of Alcoholism

An attempt was made to determine if the intensity of craving was related to the duration of alcoholism. It was found that noncravers had been alcoholics for a mean of 13.0 years, the mild cravers for 14.2 years, the moderate cravers for 10.3 years, and the severe cravers for 11.3 years. A one-way analysis of variance indicated no significant difference among the groups.

Duration of Current Abstinence

The relationship between the intensity of craving and the duration of current abstinence from alcohol was also investigated. The mean duration of abstinence for each group was as follows: noncravers, 19.4 weeks; mild cravers, 7.9 weeks; moderate cravers, 5.2 weeks; and severe cravers, 3.0 weeks. Initial inspection of the data included possible nonhomogeneity of group variances, and the Cochran C test confirmed this. Therefore, the data were transformed before the

TABLE 4
T Score Means for the Neuroticism Scale Questionnaire

NSQ Dimension	Noncravers (N=6)	Mild Cravers (N=14)	Moderate Cravers (N=16)	Severe Cravers (N=8)
Tendermindedness-overprotected	48.0	41.9	51.8	50.5
Depression-overseriousness	49.8	51.1	52.1	47.1
Submissiveness-dependence	53.7	49.6	55.9	57.0
Anxiety	51.8	60.3	63.9	66.1

one-way analysis of variance was calculated. A significant difference was found between the groups, $F(3, 40)=4.77$, $p \leq .01$, indicating a relationship between intensity of craving and duration of abstinence from alcohol. The relationship was inverse, with the severity of craving decreasing as the period of abstinence increased.

POMS Data

The POMS subscale scores were converted into T scores, and group means and standard deviations were calculated for each of the craving groups (see table 3).

A series of one-way analyses of variance was used to compare the three groups of cravers on each of the POMS subscale measures. Only the anger-hostility measure showed a significant difference among the craving groups, $F(2, 35)=3.33$, $p<.05$. It is of interest that, except for the fatigue-inertia measure, each of the POMS subscale measures was generally higher in the severe craving group than in the mild and moderate craving groups. It is also noteworthy that for the severe cravers the group means for the depression-dejection and anger-hostility subscales were more than 1 SD above the expected group mean.

The relationship between the severity of craving and POMS subscale measures was examined by means of a chi-square test comparing the craving groups in terms of the frequency of T scores above 60 across all subscales. The relationship was found to be highly significant ($\chi^2=15.22$, $df=2$, $p<.001$). The contingency coefficient assessing the degree of relationship between intensity of craving and the POMS scores was .25.

Subjects experiencing a severe craving for alcohol tended to report more severe mood changes than subjects experiencing mild and moderate craving. Finally, the mild, moderate, and severe craving groups differed significantly in mood changes involving anger-hostility.

NSQ Data

Raw data from the NSQ were converted into T scores (see table 4). A series of one-way analyses of variance was used to determine any differences among the craving groups with respect to the four NSQ measures. The craving groups were found to differ significantly only on the anxiety measure $F(3, 40)=5.03$, $p<.005$. The relationship between craving and anxiety is direct—the more intense the craving for alcohol, the greater the anxiety as measured by the NSQ. On the anxiety measure, the group mean for noncraving subjects is well within the expected normal range, while the group means for all three craving groups were at least moderately higher than the expected values. It can be concluded that among these subjects a strong relationship exists between the severity of craving and trait anxiety.

DISCUSSION

The cornerstone of the medical model of alcoholism is Jellinek's often quoted work (14). He has brought together several concepts concerning the nature of alcoholism as a disease: genetic factors, the natural course, and milestones in the natural course (craving, loss of control, amnesic spells, irreversibility, etc.). Thus he has erected a strong pillar of support for a biological model. However, several investigators have questioned the validity of the concepts used to support this pillar. Pattison (12) recently wrote an excellent review of these articles.

In the past, craving for alcohol was considered one of the strong supports for the disease concept. It was defined by many researchers as a sudden, overwhelming desire to consume alcohol that resulted from internal and possibly biological factors. However, several recent studies have supported the concept that craving is largely a conditioned response to internal and external stimuli (4, 6). Our data also tend to support this view.

The alcoholic and, to a lesser extent, the social drinker have many reasons for using alcohol—as an anxiolytic, antidepressant, euphoriant, aphrodisiac, social catalyst, confidence booster, and a means to suppress disturbing memories. Consequently, the sober alcoholic is confronted with numerous cues, both external and internal, that are capable of eliciting the craving response. The majority of subjects in the present study reported external cues as eliciting a craving for alcohol. These consisted of alcohol-related cues (48%), such as an empty beer can or a commercial for an alcoholic beverage, and non-alcohol-related events of an unpleasant (85%) or pleasant (58%) nature. Only 11 subjects reported craving associated with endogenous mood swings.

It is well known that the conditioned response extinguishes in the absence of reinforcement. We found that the frequency and intensity of craving decreased significantly with the duration of sobriety. In time, the sober alcoholic appears to learn more effective and re-

warding non-alcohol-related coping mechanisms to deal with stress. His immigration to a society of recovered alcoholics removes a number of drinking cues from his life, insulates him from other cues, propagates new insight into his drinking behavior, and provides support through this stressful period. Finally, the reminders of the "drinking days" lose their edge and slowly fade.

Our examination of sober alcoholics revealed subjects in different stages of deconditioning, ranging from those who experienced no craving (14%) to those who experienced severe craving for alcohol (18%). Such a cross-section further supports the hypothesis that craving is not necessarily an all-or-none phenomenon of a biological nature but a continuum that may be explained in terms of conditioning theory. However, our results do not rule out the possibility of a constitutional predisposition to such conditioning.

A majority of the subjects (68%) reported that association with nondrinking alcoholics was the most effective remedy for craving. Thus there is strong evidence that a substantial portion of craving is not a biological phenomenon resistant to psychological treatment. Fifteen percent of the subjects found anxiolytic drugs helpful to combat craving and 7% found relaxation useful. A large proportion (58%) used other methods including "working off steam," jogging, and having sex. This may be explained by the finding that the anger-hostility mood state differentiated mild from severe craving and that sublimation is known to be an effective means of dealing with anger. However, for 18% of the subjects craving was alcohol-specific and could be relieved only by alcohol.

An obvious corollary of the foregoing discussion is that a person who has a greater "need" for alcohol, has difficulty in keeping the craving response under control, is slow to learn new coping mechanisms, and has interpersonal difficulties, is more likely to experience severe craving. The strong relationship found between trait anxiety as measured by NSQ and the severity of craving substantiates this conclusion.

Some support for the association between depressive mood changes and alcoholism was found. Eighty-five percent of the subjects related craving to unpleasant environmental factors, 18% to endogenous depression, and 10% to endogenous elation. The mean POMS depression score for the severe cravers was more than one standard deviation above the expected mean.

In conclusion it can be said that craving, to a large extent, is a conditioned response to environmental cues. Craving tends to diminish in intensity with time and can be most effectively dealt with by psychological methods. Craving is not an all-or-none phenomenon but a continuum, with an absence of desire to drink at one pole and an intense desire at the other. Craving is most intense during the early days of sobriety and then diminishes progressively. Anxious people tend to experience more intense craving than nonanxious people.

Our data do not address the issue of whether there are two types of craving: a symbolic and a withdrawal craving (5, 6). Although there is some tentative support for the symbolic-learned hypothesis, the results do not disprove the existence of withdrawal craving. In addition, the degree to which biological factors are involved in craving remains unanswered, but there is a strong suggestion that conditioning plays a significant role.

The results reported herein should be generalized with caution to alcoholics as a group because hostel-facility clientele differ from alcoholics residing in other types of facilities on a number of psychological variables.

Drug Abuse Among Alcoholic Women

BY MARC A. SCHUCKIT, M.D., AND ELIZABETH R. MORRISSEY, M.A.

Of 293 women in an alcoholic treatment center, two-thirds had received prescriptions for drugs of potential abuse, usually hypnotic and antianxiety drugs. One-third of the women admitted abusing substances; 80% of these subjects got prescriptions for potential drugs of abuse while actively abusing. These figures are alarming in light of the lack of evidence that antianxiety drugs, hypnotics, and stimulants are effective in treating alcoholics and drug abusers. Drug-misusing women in this sample reported more suicide attempts and early antisocial problems and had received more psychiatric care than nonabusers. The authors urge that hypnotics, antianxiety drugs, and stimulants almost never be prescribed to outpatient alcoholics and that analgesics be prescribed only with great care.

PRESCRIPTION DRUG MISUSE or deliberate abuse may be a relatively common phenomenon, especially among middle- to upper-socioeconomic status (SES) individuals with complex medical histories (1). Misuse of prescription medications is even more prevalent in clinical samples of multidrug users and alcoholics. A recent review (2) indicates that somewhere between 5% and 50% of alcoholics use other drugs (average around 20%), with the chance of misuse being greater among young alcoholics (3) and in older middle-SES alcoholic women. The drugs usually misused are depressants (4, 5), which are usually obtained from physicians by prescription (5).

Most alcoholics come to their family physician with medical or emotional complaints such as sleeplessness and anxiety, a pattern said to be even more frequent among alcoholic women than men (6). The physician may respond to these nebulous complaints by prescribing hypnotics or antianxiety drugs. This is unfortunate because these two classes of drugs have not been proven to be effective when used chronically and have serious potential dangers for addiction and adverse drug interactions.

Insomnia is reported by most alcoholics and may continue for many months, either as part of the chronic alcohol-abusing picture or perhaps as a secondary abstinence phenomenon (7). However, sleeping medications tend to lose their effectiveness after 10 days to two weeks (8) and are dangerous when mixed with alcohol because they potentiate respiratory depression, with possible subsequent accidental or deliberate overdose (4). They may also interact with alcohol to increase levels of cognitive impairment in the elderly (9). Thus, hypnotics are almost contraindicated in outpatient alcoholics, as their period of effectiveness is too short and their physical dangers and abuse potential too great to justify their use.

All of the problems noted for hypnotics generalize to potential difficulties with antianxiety medication. Although anxiety can be seen during active drinking or over an extended period of time in abstinent alcoholics, controlled investigations have not demonstrated antianxiety drugs to be effective for longer than two to three weeks (10). At the same time, these depressant medications can potentiate the adverse effects of alcohol on cognition and autonomic nervous system functioning (9, 11). If these substances are taken frequently enough over a long period of time, physical dependence can be produced and, for the alcoholic, a complex withdrawal syndrome can ensue (12, 13). This is an especially difficult problem with meprobamate, a drug that also carries a high potential for overdose deaths (14).

Stimulants are the third type of drug frequently received by alcoholic outpatients. These drugs, usually prescribed for depression or lethargy (symptoms frequently seen in alcoholics), are ineffective and frequently produce subjective feelings of depression and lethargy themselves (15). Finally, care must also be taken in giving analgesics to alcoholics because of their potential drug-drug interactions with alcohol, which include increased respiratory depression and possible death (9).

The drugs most frequently abused by alcoholics are stimulants, opiates, hypnotics, and antianxiety drugs. In each instance the potential benefits are extremely limited and the risks are relatively high. Yet, due to a variety of factors, most physicians prescribe these medications to individuals who might be identified as substance misusers. We will examine one specific population of alcoholics in an attempt to document the nature and dimensions of this problem.

METHOD

The 293 subjects were drawn from 339 consecutive admissions to the King County (Seattle) Detoxification Facility in 1976. Every woman admitted was approached by a trained interviewer within 24 hours; the interview was delayed if signs of confusion were present. Four percent of the original 339 admissions refused to complete the interview, and an additional 10% were either too psychologically ill or signed out before an interview could be done.

Systematic material was collected on social and developmental histories, psychiatric syndromes as defined by Woodruff and associates (16), alcohol and drug patterns, and family history of psychiatric disorders. All data were obtained from self-reports, but the clinical records of patients were reviewed if inconsistencies occurred within the interview.

A detailed history of substance use was taken. Alcoholism or drug abuse was defined as the occurrence of a major life problem related to the use of a substance, including one of the following: a marital separation or divorce related to drugs or alcohol, multiple alcohol or drug related arrests, physical evidence that the substance had harmed health, loss of a job because of substance use, or, for drugs other than alcohol, intravenous use. As outlined by other authors (16), antisocial personality refers to the occurrence of pervasive antisocial problems beginning before age 16, and primary affective disorder indicates a persistent depression lasting for two or more weeks in the absence of preexisting alcoholism, drug use, or psychiatric disorders.

For each drug or medication, including alcohol, the individual was asked her age at first use, the frequency of occurrence of related problems, and the ages at which the first and the most recent problems occurred. In the cases of antianxiety drugs, barbiturates, amphetamines, and opiates, the patient was asked if the drug had ever been received by prescription and, if so, whether this had happened during a time when she was actively abusing other drugs or alcohol. Responses to these questions were validated by referring to the patients' reports of ages at which alcohol-related problems had occurred.

For purposes of data analysis, the women in the sample were divided into four groups. First, those who reported abusing antianxiety drugs, barbiturates, amphetamines, or opiates were separated from those who had not. Then the drug abusers were subdivided into those who abused prescription drugs and those using only "street" drugs. The nonabusers were divided according to whether they had received prescriptions for analgesics, hypnotics, antianxiety drugs, or stimulants.

Data from the interviews were numerically coded and analyzed by computer. Comparisons between groups were made using chi square, corrected for continuity where appropriate, and Student's t test for comparing means.

RESULTS

Two-thirds of the subjects had received the relevant prescription drugs: 57% received hypnotic/antianxiety medications, 27% opiates, and 22% stimulants (usually amphetamines or methylphenidate). Of the entire sample, approximately one-third met the criteria for abusing substances, including 29% who abused depressants, 27% stimulants, and 16% opiates. Eighty percent of the drug-abusing subjects who used depressants had received prescriptions for these drugs while abusing. Similarly, over half of the opiate abusers and 40% of the stimulant abusers had received prescriptions while actively abusing. Thus, between two-thirds and 90% of abusers who had received prescriptions had received them while actively abusing some substance.

Table 1 outlines the demographic and antisocial backgrounds of the four groups. The two drug-abusing populations were relatively young, the least likely to be married and most likely to have never married (es-

pecially the non-prescription drug abusers). Data not shown in the table indicate that 34% of abusers of prescription drugs, 29% of those who had received prescriptions but did not abuse them, none of the street drug abusers, and 16% of the nonabusers had been married three or more times. The women abusing nonprescription medications included the highest proportion of minorities, especially Native Americans, and had the lowest present social class.

The two drug-abusing populations demonstrated more severe alcohol histories, as shown in table 2. These women were more likely to drink daily, more frequently reported binges (drinking and disregarding usual activities for three or more days at a time), and had higher rates of all alcohol-related difficulties, including blackouts (having been alert and oriented but forgetting what one had done while intoxicated). The two groups of abusers reported the highest average number of drinks per day and were more likely to receive both outpatient and inpatient treatment for alcohol problems.

Both of the drug-abusing populations took multiple drugs, with the prescription drug abusers more likely to abuse depressants or opiates (usually oral codeine) but not stimulants. Drug-related problems were seen fairly equally for the two groups, but prescription abusers were more likely to have received medical attention for their drug problem (usually not the overt reason for seeing the prescribing physician). The prescription and nonprescription drug abusers had used each substance on multiple occasions: depressants an average of 144 and 181 times, stimulants 313 and 179 times, opiates 176 and 50 times, and cocaine 23 and 25 times, respectively.

Primary psychiatric diagnoses were based on the age of occurrence of the first appearing psychiatric disorder. As can be seen in table 3, subjects with histories of drug abuse were less likely to receive an alcoholic label and more likely to be noted as antisocial personalities or drug abusers. Almost all antisocial and drug-abusing women were secondary alcoholics. Primary affective disorder was seen in 10%–20% of each group with the exception of the nonabusing women who had not received prescriptions. Between 0% and 20% of the sample fulfilled no diagnostic criteria—most of them had alcohol-related problems that were not severe enough to meet the rather rigid criteria for this diagnosis.

Consistent with the psychiatric labels are the reports of sadness not pervasive enough to meet the criteria for affective disorder, which was seen in approximately one-quarter of the sample, especially in those having received prescriptions. Although suicide attempts were seen in all groups, they were threefold higher among the drug abusers. Also, a substantial minority of patients received outpatient or inpatient care for psychiatric problems—a trend more frequently noted for drug abusers.

The most disturbed family histories of psychiatric disorders were seen for drug abusers for all family diagnoses, especially alcoholism, as shown in table 3. In addition, 5% of the brothers and sisters of both drug-abusing groups, versus 1% of the remainder, were themselves drug abusers.

DISCUSSION

Two-thirds of the subjects received prescriptions for antianxiety drugs, hypnotics, stimulants, or opiates. Almost half of those who received prescriptions admitted to abusing them. Those drug-abusing women tended to subdivide into the younger, somewhat more antisocial "street" drug abusers and the older, relatively higher status, primarily white, abusers who took only prescription medications (17). Despite these demographic differences, both samples of abusers demonstrated an elevated rate of single marital status and high rates of antisocial problems in school, at home, and with police. In addition, the two drug-abusing populations had the heaviest alcohol use patterns, the most pervasive histories of alcohol-related life problems, and the highest rates of subsequent drug-related serious social and medical consequences.

Psychiatric disturbances, including suicide attempts, were three times as high for the abusing groups and must be considered by physicians dealing with this population. Although many subjects tended to report depression, relatively few met the criteria for primary affective disorder (16). The distinction between sadness in the midst of drug or alcohol abuse and a depressive episode of a severe nature occurring irrespective of substance problems must be kept in mind because primary affective disorder patients will probably respond to antidepressant medications, whereas the sadness noted secondary to substance abuse tends to be evanescent and does not require formal treatment (18).

Women demonstrating drug-abuse problems are more likely to consult a physician for psychological difficulties, including insomnia, depression, suicide attempts, and family or interpersonal disorganization (19), as is consistent with the data related in this study. Thus, physicians in practice are faced with a difficult dilemma. The average alcoholic is a middle-class individual who does not complain to the physician of alcohol problems but rather physical, emotional, and life difficulties. To diagnose alcoholism, one needs to have a high index of suspicion, and this is probably even more important in diagnosing drug abuse or substance misuse among alcoholics. These women are more likely to live alone, to have histories of early antisocial problems, and to report to the physician with depression, insomnia, or pain.

Hypnotics and antianxiety drugs are contraindicated in the average alcoholic. Their length of action is too short in comparison to the amount of time the patient will have symptoms to make them of use, and alcoholics should be considered at high risk for drug misuse problems. Treatment of anxiety can usually be handled by referral to an alcoholism treatment clinic, gentle understanding by the physician who sympathizes with the patient's problems, education about the probable physiologic basis of the symptoms, and warnings that any medications will cause more harm than good. Insomnia will improve with abstinence, but normal sleep patterns may not appear for a period of months (7). There are a number of nonhypnotic approaches to handling sleep problems, including exercise, establishing a rigid sleeping pattern, avoiding naps during the day, and shunning caffeinated beverages (20). Patients can be given these aids without the dangers inherent in hypnotics.

In summary, the average alcoholic is a middle-class worker or housewife consulting the physician for physical or emotional problems (6). These people, who make up one-third of the hospitalized general medical or surgical patients (21), are at high risk for abuse of hypnotics, antianxiety drugs, stimulants, and analgesics. The first three drugs should *almost never* be prescribed to this group on an outpatient basis and the latter only with great care.

Psychiatric Problems in Women Admitted to an Alcoholic Detoxification Center

MARC A. SCHUCKIT, M.D., AND ELIZABETH R. MORRISSEY, M.A.

The authors studied 293 consecutive female admissions to a public detoxification facility. One-half had a primary diagnosis of alcoholism; the rest had a primary diagnosis of affective disorder (14%), antisocial personality (14%), drug abuse (6%) or did not meet the criteria for alcoholism (13%). Each subgroup had unique social backgrounds and characteristic histories of involvement with alcohol, drugs, and antisocial problems. The primary alcoholic woman in the detoxification center resembles the primary alcoholic man in the same setting. The authors underscore the importance of socioeconomic strata and primary versus secondary diagnosis in understanding the prognosis for alcoholics.

THE COURSE OF ALCOHOLISM in women has been studied primarily in middle-class samples (1, 2), whereas most studies of male alcoholics deal with lower socioeconomic status (SES) groups, a factor that might explain many of the reported differences between alcoholic men and women (1). The two sexes also differ on histories of prior psychiatric illness, i.e., on diagnoses of primary versus secondary alcoholism (1, 3). The three predominant diagnostic groups of alcoholics—those with primary alcoholism, those with primary affective disorder and secondary alcoholism, and those with primary antisocial personality and secondary alcoholism—have different clinical pictures and prognoses (4-7). A third factor affecting comparisons of male and female alcoholics is the differential processing by public agencies; the police are less likely to confront and arrest a woman than a man for alcohol problems (8-11).

All of these factors contribute to the fact that alcohol problems in women, especially women who are public inebriates, are not clearly understood. Therefore we have studied the course of alcohol problems and the potential importance of diagnostic subgroups in women entering the King County Detoxification Center in Seattle, Washington, a facility that maintains a population of approximately 8% women.

Received June 27, 1977; revised Dec. 8, 1977; accepted Jan. 9, 1978.

At the time this work was done, Dr. Schuckit was Director, Alcoholism and Drug Abuse Institute, University of Washington, Seattle, Wash., where Ms. Morrissey is Research Consultant; he was also Associate Professor, Department of Psychiatry and Behavioral Sciences, University of Washington. Dr. Schuckit is now Director of Research, Alcohol Treatment Program, Department of Psychiatry, La Jolla VA Hospital, 3350 La Jolla Village Dr., San Diego, Calif. 92161. He is also Professor of Psychiatry, University of California, San Diego, Medical School.

METHOD

Of the 339 consecutive female admissions to the detoxification center between April and September 1976, we studied 293 (86%); 13 women refused to take part,

and 33 women were excluded during the study because of premature discharge or such serious organic brain syndromes that they could not be interviewed. Each eligible woman was given a structured interview covering demographic background, milestones of drinking, psychiatric history, drug use history, levels of social functioning, and family history of psychiatric and substance abuse problems.

The subjects were divided into groups based on their primary psychiatric diagnoses, which were assigned by the age of first occurrence of their first major psychiatric disorder. Alcoholism was defined as the occurrence of any one of a number of alcohol-related problems (12): a marital separation or divorce, multiple arrests, a job loss or layoff or inability to carry out usual tasks around the home, or physical evidence that alcohol had harmed their health. Drug abuse was defined as the presence of a similar series of drug-related problems or the use of intravenous drugs. The criteria for primary affective disorder followed those outlined by Woodruff and associates (3): a period of depression lasting at least two weeks and accompanied by changes in body functioning (e.g., insomnia, constipation, lethargy, etc.) as well as in mind functioning (e.g., inability to concentrate, mixed-up thoughts, loss of interest in things) (13). The diagnosis of a personality or sociopathy was established if, age 16, the woman had had antisocial problem of the following: family (e.g., running awa corrigibility), school (e.g., repeated truancy tiple suspensions and expulsions), police (e. tiple arrests), and peers (e.g., using weapons ing someone seriously in a fight) (14). Bec definition requires antisocial behavior in all areas prior to age 16, it was relatively easy t guish between primary sociopathy and antis havior of a limited nature secondary to alcoho misuse (6). Diagnostic criteria for other ps syndromes such as schizophrenia, Brique drome, anxiety neurosis, etc., were extracted work of Woodruff and associates (3) and Spi associates (15).

The women were divided into groups acc primary diagnosis, and their backgrounds w pared. An additional three psychiatrically ill two meeting the criteria for schizophrenia (3) having an unknown psychiatric disorder (schizophrenia), were excluded from the data a cases that would add little to the comparisons. cal analyses were made using chi square ana

RESULTS

A total of 53% of the patients met the criteria for primary alcoholism, 14% demonstrated primary affective disorder, 14% met the diagnostic criteria for primary antisocial personality, 6% had serious drug problems prior to the onset of alcohol difficulties, and 13% had no established diagnosis. Although the demographic backgrounds of these groups (table 1) were similar, the drug abusers and patients with antisocial personality were the most unusual; they tended to be young, single, and, if they had been pregnant, to have lost a child or given birth to an offspring with handicaps. These women tended to come from lower SES origins as measured by Hollingshead's Two-Factor Index of Social Position (unpublished monograph, Yale University Department of Sociology, 1957) with a striking downward SES mobility.

The alcoholic women with affective disorder were demographically similar to the primary alcoholics but tended to be more isolated and to live in geographic areas other than skid row (as determined geographically [16]). The socioeconomic status of origin for these women was relatively high and their social status mobility patterns were nearly identical to those women with no diagnoses. The primary alcoholics tended to be middle-aged, Caucasian, and separated or divorced, coming from relatively low SES origins with slight upward mobility. Over one-third of these women lived alone, with the second highest proportion residing on skid row. The no-diagnosis group was demographically similar to the primary alcoholics but more likely to have never been married, less likely to live alone, and most likely to be working full- or part-time.

The antisocial and drug use histories for the five groups are reported in table 2. Once again, the most deviant were the patients with antisocial personality and the drug abusers, both demonstrating pervasive antisocial and drug problems, even in those areas not used to establish the original diagnoses. The primary alcoholics and alcoholics with affective disorder both demonstrated intermediate rates of school problems and difficulties with the parental family and the law,

but the two groups differed on drug histories, with relatively low rates of drug abuse among the primary alcoholics and higher rates for patients with affective disorder. The no-diagnosis group had the best history of school performance and relatively low rates of school-related difficulties and problems with the parental family and drugs.

The drinking patterns and alcohol problem histories for the four groups are shown in table 3. The most serious and earliest-onset alcohol problems characterized the subjects with antisocial personality; women in this group were also the most likely to have seen a mental health worker or to have been hospitalized because of their drinking. The alcohol histories of the drug abusers were generally similar to those of the subjects with antisocial personality. The alcoholics with affective disorder, once again, were similar to the primary alcoholics in their drinking patterns, but the former were more likely to have seen a mental health worker. Although, almost by definition, the drinking patterns and problem histories of the no-diagnosis group were the most benign, they had been drinking enough for over half to have reported experiencing shakes and for many to have noted blackouts (forgetting what they had done while intoxicated but awake), auto accidents, or being arrested for alcohol-related problems. This last finding was biased by the fact that it was via auto accidents while drinking that many of these women were admitted to the detoxification center.

The psychiatric histories of the 290 subjects are given in table 4. Depressive symptoms—relatively persistent sadness that did not qualify for a diagnosis of affective disorder—were seen most frequently in the subjects with antisocial personality. The highest rates of psychiatric symptomatology and use of mental health services were for the subjects with affective disorder, but the women with antisocial personality and the drug abusers also made heavy use of such treatments and had the highest incidence of suicide attempts. Data not shown in the table indicate that the sociopaths were the only individuals to report transient psychoses, seen for 5%–10% as evanescent pictures of delusions, paranoia, or hallucinations that were not pervasive enough to warrant a diagnosis of schizo-

phrenia (3). It is also of interest that the primary alcoholics had relatively high rates of both outpatient and inpatient treatment for what may have appeared to be non-alcohol-related psychiatric problems. These occurred after the onset of alcohol abuse and although not recognized as such by the mental health professional were probably related to ethanol.

The family history data are consistent with the patient diagnostic groups. The subjects with antisocial personality had the most disordered families and had high rates of alcoholism, affective disorder, and other psychiatric disorders, usually drug or antisocial in nature. The drug abusers also reported high rates of alcoholism in fathers, with brothers showing antisocial or drug problems. The alcoholics had less disordered families, but a predominant diagnosis of alcoholism, and the no-diagnosis group had the lowest rate of ill relatives.

DISCUSSION

The women admitted to the detoxification facility were heterogeneous with respect to primary diagnosis. More than half met the criteria for primary alcoholism—a rate similar to those reported in both public and private hospital admission samples of women (4, 7, 17) and men (5). As was true in the earlier studies, only a very small percentage (about 1%) met the fairly rigid diagnostic criteria for schizophrenia.

The distribution of women with secondary alcoholism differed from previous reports on inpatient facilities. The rate of affective disorder of 14% is midway between that expected for inpatient men (about 5%) and that for women (25%). The rate of antisocial personality falls almost midway between the previously reported 5%–9% for women and 20% reported for men (4, 5), and an additional 6% met the criteria for serious drug problems.

Slightly more than one in ten of the women met no diagnostic criteria for psychiatric disorders. These patients were in their mid 40s at the time of entering the program and appeared to be a relatively heterogeneous population. Examination of individual patient records revealed that one-third of the subgroup were almost certainly not alcoholic and found their way to the detoxification center for the first time because of a first drunk driving charge, public drunkenness arrest, or because they suffered an injury at a time when they were intoxicated. However, almost two-thirds of this group were relatively heavy drinkers who did have alcohol-related problems of a somewhat limited nature. Despite their age, these women might be in the relatively early stages of alcoholism or represent a less severe course of the disorder. Certainly, underreporting might be a problem with this sample, and future follow-ups will help determine the predictive validity of assigning these women to the no-diagnosis group.

The women diagnosed as having antisocial personality were distinctive, being the youngest, coming from

the lowest SES stratum, and showing marked downward mobility despite their young age. In part by definition, they were the most deviant as children, and their problems continued into adulthood, when they were likely to drink in bars and in public places, imbibe alcohol substitutes such as perfume, demonstrate an early age of onset of drinking and related problems, and show high rates of all types of alcohol-related social difficulties and the most severe drug histories. These women do not resemble the picture of a typical alcoholic reported in the literature (1, 2, 18).

Suicide attempts were much more frequent in the antisocial personality group, which, according to the literature, were probably spur-of-the-moment attempts involving periods of frustration rather than affective episodes (19, 20). With such chaotic backgrounds, it is not surprising that the antisocial women spent much time in treatment. Follow-ups of sociopaths (14) and individuals with both alcohol and antisocial problems (7) demonstrate a poor prognosis. Thus it is important to identify these women, as they are likely to have more social difficulties within the treatment center and may show more serious antisocial problems after they are discharged, and their potentially poor prognosis must be taken into consideration in evaluating the success of treatment efforts by the center.

The 6% of the sample with primary drug abuse and secondary alcoholism were midway between the antisocial and drug/alcohol problem histories of the women with antisocial personality and those with primary alcoholism. With these women it is important to remember the necessity of dealing with other drugs of abuse as part of the treatment regimen and of taking special care regarding the probably high propensity for future antisocial problems.

In prior studies (1, 7, 13) of middle-class samples alcoholic women with histories of affective episodes before the onset of alcohol problems have been shown to have relatively unique properties. In the present study the alcoholics with affective disorder more closely resembled the primary alcoholics than was true in prior investigations, probably reflecting the lower SES of this sample. However, there was still a trend for the affective disorder alcoholics to be younger, to come from higher socioeconomic strata of origin, to be more isolated than primary alcoholics, to be less likely to get into trouble from drinking in public places, and to be less likely to live in a skid row area. The affective disorder alcoholics were also more likely than the primary alcoholics to have attempted suicide, to have seen mental health workers for non-alcohol-related problems, and to have family histories of affective disease. The importance of the affective disorder subgroup in the present sample will be determined at follow-up, but the possibility of an affective disorder subtype running higher risks for suicide attempts and having greater needs for counseling unrelated to alcohol problems should be kept in mind by anyone dealing with alcoholic women.

The primary alcoholics in many ways resemble descriptions of the male public inebriates, with an average age in the mid 40s (21), the majority being Caucasian, and one-third to one-half being separated or divorced (22). For both men and women, public inebriates have about a one-third chance of living alone and only 20% hold a job. Likewise, both groups show relatively low rates of school achievement, although a mean grade of 10.8 in the present sample of primary alcoholics was higher than the seventh- to ninth-grade education reported for most male groups (21–23). The primary alcoholic women studied here were likely to drink daily, drink rather heavily (approximately 11 drinks per drinking day), drink in public places, and have relatively high rates of alcoholic problems. Thus, primary alcoholic women were more similar to lower-class alcoholic men than to the usual sample of middle-class women. The similarity is even greater when one considers that most samples of public inebriate men (10, 24) do not control for the presence of sociopaths.

One ancillary finding is worthy of comment. These women, especially those who have drug or antisocial histories, showed very high rates of miscarriage (25%–45%), abortion (15%–33%), and having handicapped children (10%–30%). It is impossible to determine whether lifestyle, genetic propensities, or alcohol/drug abuse was responsible for this, nor can we be sure how many of these handicapped children had the fetal alcohol syndrome (25). The high probability of such a syndrome in children of heavy drinking mothers needs to be borne in mind in any attempt at meeting the social needs of this group.

A variety of factors may help explain why these women came to a detoxification center. First, most had relatively low SES classes of origin, sliding into even lower positions as their alcohol problems progressed. Within this setting, they became relatively isolated, having high rates of divorce, separation, and living alone. Also, probably related to economics, their place of residence in the skid row area, along with their lack of resources, might have made them more likely to find themselves intoxicated in public.

To further understand this population we plan to gather data on a similar sample of men at detoxification and to carry out a future follow-up of both the samples of men and women. We hope that this study will stimulate others to look at women within this population and to recognize the probable importance of diagnostic subtypes for alcoholics in any treatment facility.

Interpersonal Attractiveness and Clinical Decisions in Alcoholism Treatment

BY MICHAEL R. O'LEARY, PH.D., DENNIS M. DONOVAN, M.A., EDMUND F. CHANEY, PH.D., AND DIANE E. O'LEARY, PH.D.

The authors investigated the interactive contribution of patient characteristics and staff perceptions of the patient to decisions concerning the provision of continued alcoholism treatment following an initial 2-week evaluation period. Staff perceptions contributed significantly more to an individual's acceptance or rejection than did patient characteristics. A high interpersonal attractiveness rating also led to a significantly more positive evaluation of the patients' level of intelligence, knowledge of current events, morality, and adjustment. The present results and research findings with general psychiatric populations are compared.

DECISION-MAKING in the areas of clinical judgment, diagnosis, and the provision of treatment service, although of obvious importance, is still poorly understood (1). In any conceptualization of the clinical decision-making process, three main classes of variables must be considered: client or patient characteristics, characteristics of the health care provider, and the resulting interaction. While client and therapist variables have often been investigated independently, the study of the interaction between these two classes has been rare (1, 2).

The client variable that has received the most intensive investigation has been social class, typically defined in terms of occupational status, income, and/or educational achievement. In reviewing a large body of early literature on client characteristics, Garfield (2) concluded that social class variables were more predictive of both acceptance into and duration of psychotherapy than were personality variables. The results of early epidemiological studies (3, 4) and more recent analogue investigations (1) show a relatively consistent pattern: upper- and middle-class clients are more likely to be judged favorably, are more likely to be accepted into treatment, and are likely to receive more extensive care. The effects of social class may be mediated by the evocation of certain stereotypic biases among treatment personnel (1, 5). Stern (5), summarizing the relevant literature, indicated that staff members in many psychiatric facilities believe that persons of high social class possess attitudes and abilities which allow them to benefit maximally from individual psychotherapy. For instance, Brill and Storrow (6) found that lower social class status was significantly related to therapist evaluations of low estimated intelligence, a tendency for clients to view their problems as physical rather than emotional, a desire for symptomatic relief, and a lack of understanding of and desire for psychotherapy. The intake interviewer had less positive feeling toward lower-class patients and saw them as less treatable by means of psychotherapy than middle-class patients.

Strupp and his coworkers (7, 8) evaluated staff members' interpersonal attraction toward clients and found that the interviewer's liking for the patient as a person was positively related to judgments concerning the clients' emotional maturity, motivation for treatment, expected level of improvement in therapy, and recommendations for insight-oriented therapy. Furthermore, liking the client was inversely related to ratings of hostility, defensiveness, and the degree of disturbance. Such findings, taken together, suggest that variables such as client social status and a therapist's perception of a client's interpersonal attractiveness may operate interactively to influence decision making in diagnosis, acceptability for treatment, and the nature of treatment.

Blane (9) has indicated that client characteristics generally bear the same association to treatment for alcoholics that holds for general psychiatric patients. Smart and associates (10) noted that the patient's social class was chief among factors extraneous to alcoholic clients' personality and disease process, which influenced the type of service provided. Socioeconomic status and social stability also appeared to be positively related to treatment outcome (11–16).

In contrast to the relatively well-documented effects of client characteristics on the selection for and out-

Portions of this paper were presented at the 58th annual meeting of the Western Psychological Association, San Francisco, Calif., April 19-22, 1978.

Mr. Donovan is a doctoral candidate in Clinical Psychology, Department of Psychology, University of Washington. Dr. D. O'Leary is Clinical Psychologist, Bremerton Psychiatric Clinic, Bremerton, Wash.

come of alcoholism treatment, relatively little information is available concerning the effects of therapist characteristics or therapist-client interactions. Therapist variables are potentially crucial to the successful treatment of the alcoholic. They include such background characteristics as age, sex, and therapeutic experience, as well as psychological factors such as receptivity to treating alcoholics and interpersonal attraction (9). Furthermore, it has been suggested (9, 17, 18) that the interaction between client and therapist variables may have its maximum impact during the initial stages of treatment and may contribute to premature treatment termination. However, there is little empirical support for these contentions.

The purpose of the present study was to investigate the relative contribution of patient and treatment staff variables to clinical decisions to offer continued inpatient therapy to alcoholics following a two-week evaluation period. The patient variables included measures of social class and demographic characteristics, personality functioning, and the client's perception of the treatment ward atmosphere. The staff variable under consideration was the treatment personnel's attitude toward the clients, measured by ratings of their perceived interpersonal attractiveness. Based on the pattern of results found with general psychiatric populations, we anticipated that the major contributors to the decision concerning continued treatment would be the patients' social status and the staff members' ratings of the clients' interpersonal attractiveness; client personality variables were expected to have less influence on the decision process.

METHOD

Subjects

The subjects were 50 consecutive admissions to the inpatient phase of an alcoholism treatment program. Prior to admission the subjects, all males, were screened for gross evidence of severe thought disorder, psychotic symptoms, and organic brain syndrome. The primary diagnosis for each patient was alcohol addiction. The sample had a mean age of 45.08 years (SD=10.57) and a mean education level of 12.60 years (SD=2.66). All subjects provided informed consent to participate in the research after the procedures of the study were fully explained.

Treatment Setting

The research was conducted in the alcoholism treatment program of the Seattle Veterans Administration Medical Center. The primary treatment staff consisted of a multidisciplinary team composed of a psychiatrist, a clinical psychologist, social workers, a vocational rehabilitation specialist, alcoholism counselors, and nursing personnel. The therapeutic regimen consisted largely of interpersonal skills training and small-group therapy with a process orientation (19), both within the broader framework of a therapeutic community. Psychological theories of alcoholism development and maintenance were stressed; patients were helped to focus on the contingencies contributing to their drinking behavior and were encouraged to take responsibility for making life changes necessary to increase the probability of their achieving abstinence and overall social and personal adjustment. Following admission, and detoxification if necessary, patients completed a 2-week evaluation period. At the end of this period the staff consensually decided whether or not to offer the patient continued treatment, i.e., 3 more weeks of inpatient treatment followed by 1 month of day treatment and 9 months in a weekly aftercare group.

Patient Measures

The clients' age, educational level, and social status were employed as primary demographic variables. Hollingshead and Redlich's procedure (3) was used to generate a two-factor index of social position (the sum of the weighted scaled scores for occupational and educational levels), which was then converted into one of five levels of social class. Higher scores on each of these variables is related to a lower social status.

A variety of personality and cognitive tests was completed by the patients approximately 10 days following admission. The Minnesota Multiphasic Personality Inventory (MMPI) provided a measure of generalized psychopathology. Schutz's FIRO-B test (20) was given to assess the clients' orientation toward interpersonal relationships. The scale measures three basic dimensions of interpersonal relationships: inclusion, control, and affection (21). Inclusion assesses the degree to which a person associates with others. Control measures the extent to which the individual assumes responsibility, makes decisions, and dominates people. Affection assesses the degree to which a person becomes emotionally involved with others. Each of these three dimensions is further differentiated into two subscores reflecting expressed or manifest behavior versus wanted or desired behavior.

Rotter's internal-external locus of control scale (22) was employed as a measure of the general level of personal responsibility the individual assumes for his/her behavior. A low score on the scale reflects the individual's perception that the outcome of significant life events is contingent on personal initiative and action. A specially constructed drinking-related locus of control scale was also included (23, 24). An external score on the scale has been found to be related to increased levels of physical, psychological, and social impairment due to chronic drinking (24).

Intellectual functioning was assessed by the Shipley-Hartford Scale (25) and the Trail Making Test (26). Measures of verbal ability, abstracting ability, cognitive impairment (Conceptual Quotient), and general intelligence (IQ) were derived from the Shipley-Hartford Scale. Higher scores on each of these measures indicate a higher level of cognitive functioning. Higher scores on the two portions of the Trail Making Test

(parts A and B) indicate higher levels of cognitive impairment.

On the day the staff members were to make their decision concerning continued treatment, the patient completed the Ward Atmosphere Scale (WAS), Form R (27, 28), which assesses the patient's perception of the social climate of the treatment unit. The scale measures 10 dimensions of the ward atmosphere falling within 3 broad categories. The first, including the involvement, support, and spontaneity subscales, measures aspects of patient and staff relationships. The next four subscales, autonomy, practical orientation, personal problem orientation, and anger and aggression, measure personal development and the program's treatment orientation. The final scales, order and organization, program clarity, and staff control, assess system maintenance dimensions.

Staff Measures

Prior to discussing a particular patient's clinical status and reaching a consensual decision concerning his suitability for continued treatment, each member of the primary treatment team rated the patient on Byrne's Interpersonal Judgment Scale (IJS) (29). The IJS consists of 6 subscales (intelligence, knowledge of current events, morality, adjustment, personal feelings of likability, and working together in a group). Staff members were to express their opinions about and evaluations of the patient by rating on each of the 7-point subscales. The first 4 items deal with various aspects of personal evaluation. The last 2 items deal specifically with interpersonal attractiveness.

Following the completion of the IJS scales, the staff members discussed the patient's case and arrived at a decision concerning continued treatment. The outcome of this staff decision was used to classify the subjects as accepted or rejected for the purposes of the present analysis. Of the 50 subjects, 22 (44%) were rejected and 28 (56%) were accepted.

RESULTS

The 6 primary staff members' ratings for each patient were averaged to provide an overall evaluation of the individual on each of the 6 IJS subscales. A patient's total interpersonal attraction score was then derived by averaging the sum of the staff's scores on the personal feelings of likability and working together in a group subscales. These IJS subscale scores, as well as all of the other patient personality and demographic variables, were evaluated by means of one-way analyses of variance for the accepted and rejected patients.

The results of this analysis indicate that the patient variables related minimally to the decision concerning treatment disposition. Of the 40 patient variables, only 4 significantly differentiated between the accepted and rejected groups. Those patients who were selected for continued treatment had a significantly higher educational level ($p<.05$), a greater need for others to initiate close, intimate relationships with them (FIRO-B, Want Affection scale) ($p<.01$), a higher level of ego strength ($p<.05$), and a higher level of functional defensiveness (MMPI K scale) ($p<.05$). No differences were found between groups on age, social class, cognitive functioning, general or drinking-specific locus of control, perception of ward atmosphere, or other measures of interpersonal and psychological function.

TABLE 1
Accept and Reject Rates Based on Staff Ratings on Interpersonal Judgment Scale

IJS Variables	Low Level (%)		High Level (%)			
	Accept	Reject	Accept	Reject	χ^{2a}	ϕ
Intelligence	22.0	30.0	34.0	14.0	3.05	.29
Current events	18.0	32.0	38.0	12.0	6.57[b]	.40
Morality	20.0	28.0	36.0	16.0	2.81	.28
Adjustment	20.0	28.0	36.0	16.0	2.81	.28
Likability	12.0	36.0	44.0	8.0	15.66[c]	.60
Group membership	10.0	38.0	46.0	6.0	20.50[c]	.68

[a]Yates' correction applied.
[b]$p<.01$.
[c]$p<.0001$.

In contrast to the relative noncontributory nature of these patient variables, the staff ratings on the Interpersonal Judgment Scale significantly differentiated between the two groups. Subjects who were accepted for treatment were rated as being more intelligent ($p<.05$), having a greater knowledge of current events ($p<.05$), having higher moral standards ($p<.01$), and being better adjusted ($p<.01$). Furthermore, accepted patients were seen as being more interpersonally attractive by the staff, as indicated by the significantly higher ratings of personal likability and suitability for group membership ($p<.01$).

The relationship of the individual IJS variables to the acceptance or rejection of patients was further evaluated by 2×2 chi-square analyses. Subjects were classified as falling above (high level) or below (low level) the median on each of the IJS subscales. The percentage of subjects within each of these categories who were accepted or rejected is found in table 1. Of the IJS subscales, the perceived level of knowledge of current events, the staff's liking of the patient as a person, and the judged suitability for group membership were the most predictive of the staff decision process.

A stepwise multivariate discriminant functions analysis (30) was conducted to determine that combination of variables which provided the greatest level of differentiation between the accepted and rejected patient groups. The 9 most discriminating original variables were entered into this analysis based on the results of the initial analysis of variance. These variables were the patient's educational level, MMPI K and ego strength scales, the FIRO-B Want Affection score, the 4 evaluative subscales of the IJS, and the total interpersonal attractiveness score. The patient's social position index was also included in order to determine the multivariate contribution of this variable. The results indicated that 3 of the 10 variables made signifi-

cant contributions to this discrimination: total interpersonal attractiveness ($p<.001$), wanted affection ($p<.002$), and ego strength ($p<.02$).

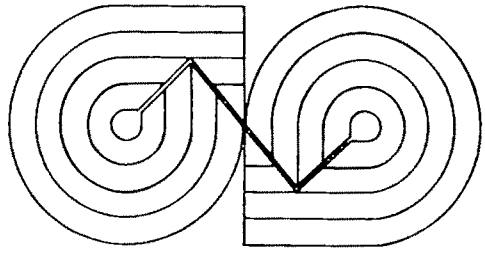
DISCUSSION

Garfield (2) noted that not all individuals who apply for psychotherapeutic help receive it, and not all individuals who are offered psychotherapy accept it. Previous research in the area of clinical decision making has found that a major determinant of the outcome of such decisions is the patient's social status (1–4, 6). It had been assumed that lower-class clients had values, attitudes, and conceptions concerning treatment that differed from those of middle-class clients, as well as therapists, which interfered with their active participation in the therapeutic process. More recent findings have challenged these assumptions. Frank and associates (31) found that the conceptions clients have concerning therapy is highly similar across social classes. Stern (5) also found that client social status was not related to acceptance into treatment, assignment to different forms of treatment, or to the number of therapeutic sessions provided. It has been suggested (5, 31) that this discrepancy between the older body of literature, collected primarily in the 1950s and 1960s, and more recent findings may be related to relatively widespread societal changes in attitudes toward mental illness and the increased availability of professional services to all levels of social class.

Our results with alcoholics in an inpatient rehabilitation program also tend to be discrepant from earlier findings. Prior research indicated that the social class of alcoholic subjects exerted a great degree of influence on acceptance into treatment, type of therapy assignment, and outcome (9-16). However, the present findings do not support the pervasiveness of social class influence. We found that alcoholics' social position did not contribute significantly to staff decisions concerning the provision of continued treatment. A possible interpretation for this finding is that patients within the Veterans Administration system are drawn from a relatively low and restricted range of social class; however, an examination of the two-factor social position index indicates that while the mean for the present sample fell within class IV (a mean of 52.5 out of a possible range from 11 to 77), the sample was also characterized by a high degree of variability ($SD=12.3$).

It may be that with an increased emphasis being placed on the provision of therapeutic services to a broadly based constituency, both within the VA and community mental health systems, the potentially biasing influence of social class is diminishing. If social class played a minimal role in clinical decisions concerning the provision of treatment, what other factors may have affected this decision? Patient's personality characteristics appeared to play a limited role. Of the 40 demographic, personality, and cognitive variables investigated, only 4 were found to differentiate between those alcoholics accepted or rejected for continued therapy. Those individuals accepted for treatment were better educated, desired others to initate close, intimate relationships with them, presented themselves in a more positive light, and had a higher level of ego strength; this latter scale has been shown in previous research to be predictive of prognosis in psychotherapy (32).

The variable found to be most predictive of staff members' decisions was their perception of the patient's interpersonal attractiveness. Those individuals who were judged to be highly attractive on an interpersonal level, as defined by staff ratings of their personal likability and suitability for group membership, were highly likely to be accepted for continued treatment. This finding is consistent with the suggestion of Smart and associates (10) that a number of factors extraneous to the alcoholic patient's personality characteristics and disease state may influence treatment-related decisions. The primary variable appears to be the staff members' collective attitude toward the patient rather than psychometrically measured patient characteristics.



The present findings may be reflective not so much of social class as of the professional relationship between staff and patient. One might speculate that therapists rate as likable those types of patients who, in their experience, are most likely to benefit from the therapeutic modalities at which they are most skilled, thus reinforcing the therapists' sense of professional effectiveness. Thus, ratings of likability may have objective behavioral correlates that are at least partially independent of social class biases.

We have attempted to determine how alcoholics' personal characteristics and staff members' perceptions interact to influence aspects of treatment at the entry boundary of a therapeutic system. Continued research is needed in this area (9, 17, 18) as well as in attempts to determine the effects of such interactions on assignment to differing treatment modalities and on therapeutic outcome. If these findings are replicated in other mental health settings as a stable feature of clinical decision making, they have important implications for training and education programs in psychiatry and the behavioral sciences.

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

a valuable link to the resources of the American Psychiatric Association

for institutions and agencies concerned with the care of the mentally disabled

Enrollment in the Hospital & Community Psychiatry Service brings multiple copies of *Hospital & Community Psychiatry* into member agencies every month, keeping staff up to date on developments and issues in the mental health field, offering new ideas and fresh perspectives, and serving as a useful resource in staff development and training programs.

Hospital & Community Psychiatry is just one of the benefits of membership in the H&CP Service. Others include a film library containing more than a hundred films specially chosen for their usefulness in staff development and community education programs; supplementary mailings of important books, reports, articles, or other material of special interest to administrators or clinicians; reduced registration fees at the annual fall Institute on Hospital & Community Psychiatry; and, on request, information and consultation from the professional staff of the American Psychiatric Association. The H&CP Service also sponsors the annual Achievement Awards competition, which gives special recognition to outstanding programs for the mentally ill and mentally retarded.

Please send me information about membership in the Hospital & Community Psychiatry Service.

many patients,

THE RIGHT ANTIDEPRESSANT

No tricyclic antidepressant works more effectively to brighten the mood, relieve sleep disturbances, and ameliorate mild anxiety.[1] And none appears to be better balanced[2] in terms of the biogenic amine theory of depression, which relates depression to functional deficiencies of the catecholamines.

For Tofranil-PM is almost equally effective in inhibiting the postsynaptic uptake of both norepinephrine and serotonin, the two neurotransmitters most often implicated in depression, while other tricyclic antidepressants tested are heavily skewed towards one or the other.*

*Nortriptyline, a chemical derivative of amitriptyline, also exhibits balanced action, but does not appear as effective in treating serotonin-mediated depression as imipramine.

Please see last page for a brief summary of the prescribing information.

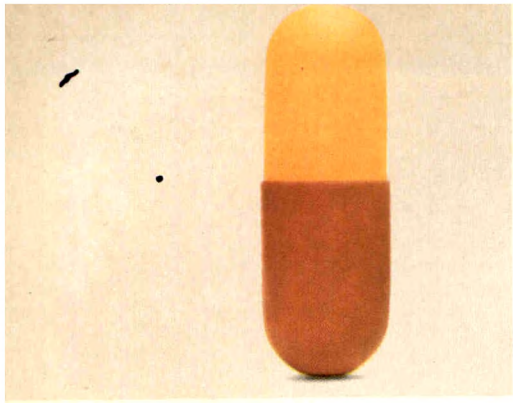
anxiety-depression,

THE RIGHT

Geigy

COMBINATION*...

Although Tofranil-PM provides a sedative effect, when you decide to add a tranquilizer for more control of the anxiety, you can confidently prescribe clorazepate dipotassium with Tofranil-PM.



Tofranil-PM is effective when used alone or with virtually any benzodiazepine selected—a flexibility difficult to achieve with fixed-combination antidepressant regimens.

The decision of which drugs to combine, and at what dosages, remains entirely in your hands . . . where it belongs.

* The actions of benzodiazepines may be potentiated by concomitant use with Tofranil-PM. Careful consideration should be given to the pharmacology of the agents in any such combination before prescribing.

Please see last page for a brief summary of the prescribing information.

† Tranxene, a product of Abbott Laboratories

for many patients, the right antidepressant, alone... or the basis of the right combination

Tofranil-PM® imipramine pamoate ...unsurpassed antidepressant action

For the majority of patients with neurotic depression, Tofranil-PM may be the only drug needed to produce a satisfactory brightening of mood.[1] Recent evaluation notes that the two leading single-entity tricyclic antidepressants—imipramine pamoate (Tofranil-PM) and amitriptyline—provide equally effective antidepressant activity.[3]

toward a better quality of sleep —usually without morning "hangover"

A recent study[3] compared the effectiveness of once-nightly imipramine pamoate and amitriptyline in 57 neurotically-depressed outpatients with sleep disturbances. The overall findings indicate both drugs were equally effective in treating neurotic depression, with patients on Tofranil-PM tending to have a better quality of sleep. The difference was not statistically significant.

Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg of imipramine hydrochloride.

Many patients show good results on Tofranil-PM 75 mg h.s.; however, higher doses may be necessary.

imipramine pamoate

Capsules of 75 mg
Capsules of 100 mg
Capsules of 125 mg
Capsules of 150 mg
For oral administration

Each 75-mg capsule contains imipramine pamoate equivalent to 75 mg of imipramine hydrochloride.
Each 100-mg capsule contains imipramine pamoate equivalent to 100 mg of imipramine hydrochloride.
Each 125-mg capsule contains imipramine pamoate equivalent to 125 mg of imipramine hydrochloride.
Each 150-mg capsule contains imipramine pamoate equivalent to 150 mg of imipramine hydrochloride.

Brief Summary of Prescribing Information

Indications For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states. One to three weeks of treatment may be needed before optimal therapeutic effects are evident.

Contraindications The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed.

The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings Extreme caution should be used when this drug is given to:

- —patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, congestive heart failure, myocardial infarction, strokes and tachycardia. These patients require cardiac surveillance at all dosage levels of the drug;
- —patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
- —hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
- —patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
- —patients receiving guanethidine, clonidine, or similar agents, since imipramine pamoate may block the pharmacologic effects of these drugs;
- —patients receiving methylphenidate hydrochloride. Since methylphenidate hydrochloride may inhibit the metabolism of imipramine pamoate, downward dosage adjustment of imipramine pamoate may be required when given concomitantly with methylphenidate hydrochloride.

Since imipramine pamoate may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as operating an automobile or machinery, the patient should be cautioned accordingly.

Tofranil-PM may enhance the CNS depressant effects of alcohol. Therefore, it should be borne in mind that the dangers inherent in a suicide attempt or accidental overdosage with the drug may be increased for the patient who uses excessive amounts of alcohol. (See **Precautions**.)

Usage in Children: Tofranil-PM should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg, 100 mg, 125 mg and 150 mg). Each capsule contains imipramine pamoate equivalent to 75 mg, 100 mg, 125 mg or 150 mg imipramine hydrochloride.

Precautions An ECG recording should be taken prior to the initiation of larger-than-usual doses of imipramine pamoate and at appropriate intervals thereafter until steady state is achieved. (Patients with any evidence of cardiovascular disease require cardiac surveillance at all dosage levels of the drug. See **Warnings**.) Elderly patients and patients with cardiac disease or a prior history of cardiac disease are at special risk of developing the cardiac abnormalities associated with the use of imipramine pamoate. It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with imipramine pamoate and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, imipramine pamoate may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes. An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine. Concurrent administration of imipramine pamoate with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Usage During Pregnancy and Lactation:
Animal reproduction studies have yielded inconclusive results.

There have been no well-controlled studies conducted with pregnant women to determine the effect of imipramine on the fetus. However, there have been clinical reports of congenital malformations associated with the use of the drug. Although a causal relationship [illegible] these effects and the drug could not be establis[illegible] possibility of fetal risk from the maternal ingestio[illegible] imipramine cannot be excluded. Therefore, imip[illegible] should be used in women who are or might bec[illegible] pregnant only if the clinical condition clearly just[illegible] potential risk to the fetus.

Limited data suggest that imipramine is likely to [illegible] creted in human breast milk. As a general rule, [illegible] woman taking a drug should not nurse since the [illegible] possibility exists that the drug may be excreted [illegible] breast milk and be harmful to the child.

Patients should be warned that imipramine pam[illegible] may enhance the CNS depressant effects of alc[illegible] (See **Warnings.**)

Imipramine pamoate should be used with cautio[illegible] patients with significantly impaired renal or hep[illegible] function.

Patients who develop a fever and a sore throat [illegible] therapy with imipramine pamoate should have [illegible] cyte and differential blood counts performed. In[illegible] ramine pamoate should be discontinued if there[illegible] dence of pathological neutrophil depression.

Prior to elective surgery, imipramine pamoate sh[illegible] be discontinued for as long as the clinical situa[illegible] allow.

In occasional susceptible patients or in those re[illegible] anticholinergic drugs (including antiparkinsoni[illegible] agents) in addition, the atropine-like effects ma[illegible] come more pronounced (e.g., paralytic ileus). [illegible] supervision and careful adjustment of dosage [illegible] quired when imipramine pamoate is administer[illegible] comitantly with anticholinergic drugs.

Avoid the use of preparations, such as decong[illegible] and local anesthetics, which contain any sympa[illegible] mimetic amine (e.g., epinephrine, norepinephr[illegible] since it has been reported that tricyclic antidep[illegible] can potentiate the effects of catecholamines.

Caution should be exercised when imipramine [illegible] oate is used with agents that lower blood press[illegible] Imipramine pamoate may potentiate the effects [illegible] depressant drugs.

Patients taking imipramine pamoate should av[illegible] cessive exposure to sunlight since there have b[illegible] ports of photosensitization.

Both elevation and lowering of blood sugar lev[illegible] been reported with imipramine pamoate use.

Adverse Reactions Note: Although the listing [illegible] follows includes a few adverse reactions which [illegible] not been reported with this specific drug, the p[illegible] macological similarities among the tricyclic ant[illegible] sant drugs require that each of the reactions be[illegible] ered when imipramine is administered.

Cardiovascular: Orthostatic hypotension, hype[illegible] tachycardia, palpitation, myocardial infarction, [illegible] mias, heart block, ECG changes, precipitation [illegible] gestive heart failure, stroke.

Psychiatric: Confusional states (especially in t[illegible] derly) with hallucinations, disorientation, delusi[illegible] iety, restlessness, agitation; insomnia and nigh[illegible] hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesia[illegible] tremities; incoordination, ataxia, tremors; perip[illegible] neuropathy; extrapyramidal symptoms; seizure[illegible] tions in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associ[illegible] lingual adenitis; blurred vision, disturbances o[illegible] commodation, mydriasis; constipation, paralyt[illegible] urinary retention, delayed micturition, dilation [illegible] nary tract.

Allergic: Skin rash, petechiae, urticaria, itching[illegible] sensitization; edema (general or of face and t[illegible] drug fever; cross-sensitivity with desipramine.

Hematologic: Bone marrow depression includi[illegible] agranulocytosis; eosinophilia; purpura; thromb[illegible] penia.

Gastrointestinal: Nausea and vomiting, anorex[illegible] epigastric distress, diarrhea; peculiar taste, st[illegible] abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast [illegible] ment and galactorrhea in the female; increase[illegible] creased libido, impotence; testicular swelling; [illegible] or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); alte[illegible] function; weight gain or loss; perspiration; flus[illegible] nary frequency; drowsiness, dizziness, weakn[illegible] fatigue; headache; parotid swelling; alopecia; [illegible] ness to falling.

Withdrawal Symptoms: Though not indicative [illegible] tion, abrupt cessation of treatment after prolon[illegible] therapy may produce nausea, headache and [illegible]

How Supplied Tofranil-PM is available as follo[illegible] 75-mg, coral-colored capsules equivalent to [illegible] imipramine hydrochloride in bottles of 30, 100[illegible] 1,000 capsules, and unit strip packages of 10[illegible] 100-mg, dark yellow/coral-colored capsules e[illegible] to 100 mg imipramine hydrochloride in bottles [illegible] and 1,000 capsules.

125-mg, light yellow/coral-colored capsules e[illegible] to 125 mg imipramine hydrochloride in bottles [illegible] and 1,000 capsules.

150-mg, coral-colored capsules equivalent to [illegible] imipramine hydrochloride in bottles of 30, 100[illegible] capsules, and unit strip packages of 100.

For complete details, including description, a[illegible] dosage and administration, and overdosage, see full prescribing information.

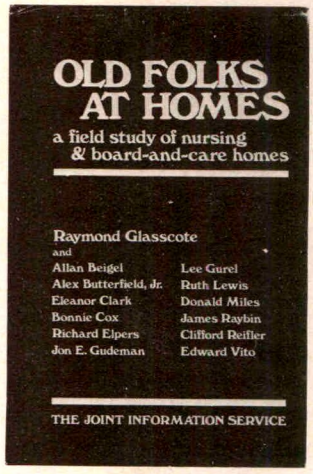
The Joint Information Service of the American Psychiatric Association and the Mental Health Association releases Two New Volumes That

Focus on the Elderly



This carefully documented book reports a field study of ten programs, four in America and six in England and Scandinavia, which serve as practical demonstrations of creative mental health services for the elderly. They include:

- a novel "Neighborhood Family" providing vigorous support to elderly residents of several trailer parks
- a high school for the elderly which sends its students abroad for study trips
- a "Human Development Project" that focuses on responding to the psychological needs of the elderly
- a carefully coordinated system of "respite hospitalization," which promotes the health of the elderly while allowing maximum use of hospital beds and family resources
- a "Lucy Booth," patterned after the Peanuts comic strip, which provides easy access to many kinds of services
- and many other innovative, successful approaches.

Each program is subjected to intensive scrutiny. The resulting document becomes a handbook, and, as well, a forum through which some of the world's most experienced practitioners of "the psychiatry of old age" present their views.

Dr. Wilma Donohue, director of the International Center for Social Gerontology, characterizes this volume as "a masterful job of putting everything in relief . . . the guidelines for action are right here."

190 pages. Casebound. Price $8.50.

Concerned about the very bad reputation that nursing homes have received from many quarters in recent years, the Joint Information Service set up a field study to visit a systematically chosen sample of nursing homes, and board-and-care homes as well, to see to what extent the care of and the quality of life for the patients differed from the geriatrics units of state hospitals. Altogether, sixty nursing homes and 31 board-and-care homes in ten locales were visited, in each case by the senior author accompanied by two mental health professionals.

The teams were surpised to learn that care and quality of life in many of the nursing and board-and-care homes they visited were better—sometimes dramatically better—than that in the mental health facilities and often at lower cost.

This unique publication provides an overview of all facilities visited plus vignettes of approximately half. Federal and state rules and regulations are also expertly synthesized into brief and readable style.

148 pages. Casebound. Price $6.50

Divide scored Endep tablets

+

Add flexibility to dosage titration

Long term treatment of depression with amitriptyline requires precise calculation of dosage to meet the individual needs of each patient. Because all six strengths of Endep are scored, you can easily increase or decrease dosage in half-tablet steps, without the bother and expense of a new prescription.

−

Subtract waste and cost

Scored Endep tablets permit you to adjust the regimen without wasting unused tablets or burdening the patient with the cost of a new prescription.

×

Multiply therapeutic options

The pharmacokinetic properties of Endep are such that its clinical effect is the same whether prescribed *t.i.d.* or as a single daily dose. Thus, once you have established the proper dosage, you can prescribe the entire dose *h.s.*, minimizing anticholinergic and sedative side effects, and helping to assure patient compliance with this simple regimen.

By prescribing the higher strength tablets *h.s.*— secure in the knowledge that the dosage can be adjusted without resorting to a new prescription—your patient will economize further on a per milligram basis.

Endep®
amitriptyline HCl/Roche

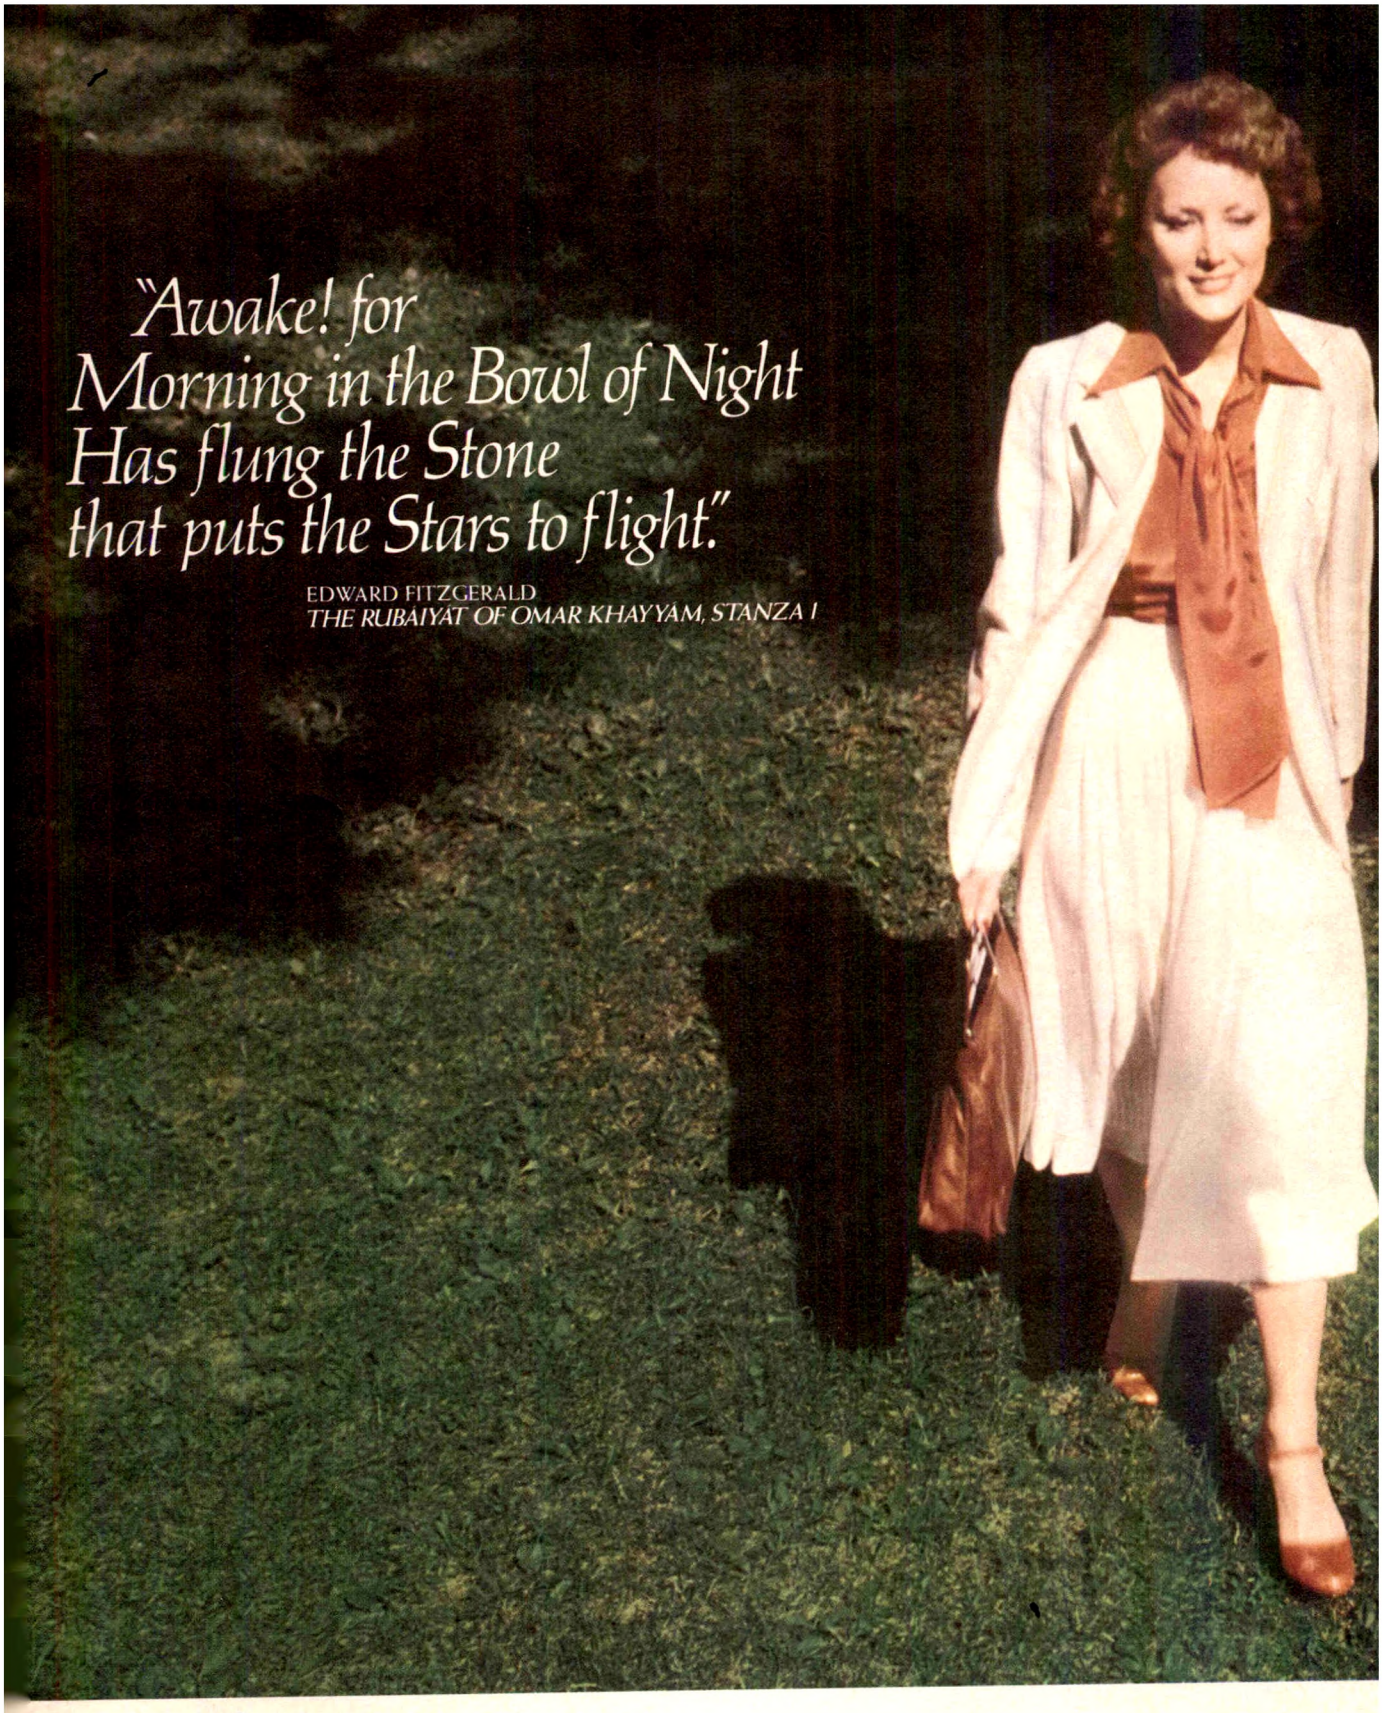
The only antidepressant scored for easy division

Endep
amitriptyline HCl/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.

Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle-closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh possible benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.



Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Supplied: *Scored Tablets:* 10, 25, 50, 75, 100, 150 mg.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

Brief Summary of Prescribing Information

ADAPIN® (doxepin HCl) Capsules

Indications—Relief of symptoms of anxiety and depression.

Contraindications—Glaucoma, tendency toward urinary retention, or hypersensitivity to doxepin.

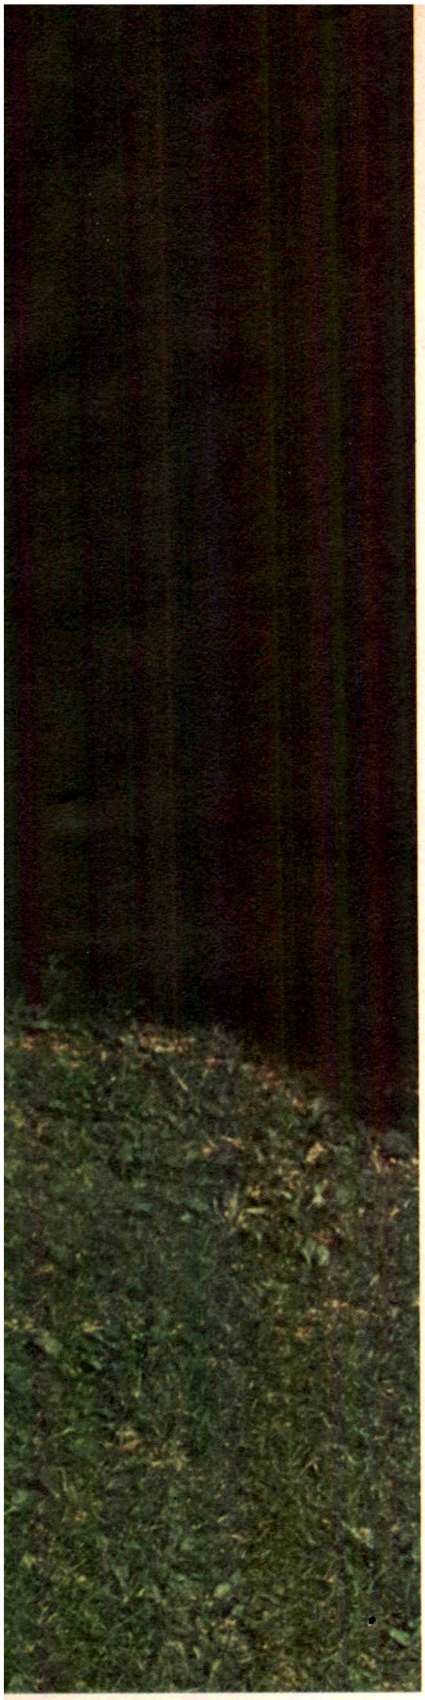
Warnings—Adapin has not been evaluated for safety in pregnancy. No evidence of harm to the animal fetus has been shown in reproductive studies. There are no data concerning secretion in human milk, nor on effect in nursing infants.

Usage in children under 12 years of age is not recommended. MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug, as serious side-effects and death have been reported with the concomitant use of certain drugs and MAO inhibitors.

In patients who may use alcohol excessively potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions—Drowsiness may occur and patients should be cautioned against driving a motor vehicle or operating hazardous machinery. Since suicide is an inherent risk in depressed patients they should be closely supervised while receiving treatment. Although Adapin has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind.

Adverse Reactions—Dry mouth, blurred vision and constipation have been reported. Drowsiness has also been observed.



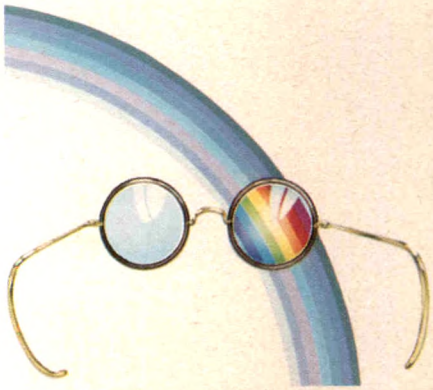
Adverse effects occurring infrequently include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as sweating, tachycardia and hypotension. Weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash and pruritus may a occur.

Dosage and Administration—In mild to moderate anxiety an depression: 25 mg t.i.d. Increase or decrease the dosage accor to individual response. Daily dosage, up to 150 mg may be take bedtime without loss of effectiveness. Usual optimum daily dos is 75 mg to 150 mg per day not to exceed 300 mg per day.

Antianxiety effect usually precedes the antidepressant effec two or three weeks.

How Supplied—Each capsule conta s doxepin, as the drochloride: **10 mg, 25 mg, 50 mg, and 00 mg** apsules in bo of 100 and 1000.

For complete prescribing information please e package in or PDR.



in anxiety/depression...

a good awakening from a good night's sleep

Most depressed patients experience some form of sleep disturbance. Adapin® helps relieve the accompanying anxiety, and restores a more normal sleep pattern right from the start of therapy.

☐ **convenient, flexible therapy**
The usual optimal dose is 75 to 150 mg daily. The entire dose may be given at night without loss of therapeutic effect. Adapin is available as 10 mg, 25 mg, 50 mg, and 100 mg capsules.

MANUAL OF PSYCHIATRIC PEER REVIEW

by the Peer Review Committee of the American Psychiatric Association, Donald G. Langsley, M.D., Chairperson in cooperation with the Joint Task Force on Diagnostic Criteria for Analyzability of the American Psychoanalytic Association, William Offenkrantz, M.D., Chairperson, and the Peer Review Committee of the American Academy of Child Psychiatry. Larry B. Silver, M.D., Chairperson.

"This Manual provides a set of guidelines for district branches of APA and their peer review committees which should be adapted and modified in terms of local criteria, standards, and practices. The guidelines are not intended to be hard and fast rules. They are screening criteria, and not regulations to control practice. They are so designed that they can be utilized by non-physicians to identify those cases that can profitably be reviewed by psychiatrists serving on peer review committees. This document should be viewed as transitional, subject to revision as experience is gained, and continually updated in response to advances in psychiatric knowledge and changes in patterns of practice. . . . The application of these standards, and refinement through experience must rest with the peer review committees of district branches. . . . It should help them to move ahead in the development of a peer review for American psychiatry."

Robert W. Gibson, M.D.
President

Part I titled PSYCHIATRIC PEER REVIEW contains sections on Basic Relationships and Responsibilities, Appointment of Peer Review Committees, Funding, Operations and Procedures, Medical Care Evaluation Studies, Appeals Processes, Special Problems, Confidentiality, Educational Aspects, Medical Ethics, Advocacy, Interdisciplinary Aspects, with Appendices on Model Screening Format for Inpatient Treatment for Alcoholism, Model Screening Format for Outpatient Treatment, Sample Form for Requesting Extension of Office Treatment, Claims Review Guidelines Suggestions, APA Position Papers on Peer Review, Bibliography.

Part II titled PSYCHOANALYTIC PEER REVIEW has sections on Steps in Peer Review for Psychoanalysis, Guidelines for Model Criteria Sets, Pilot Application of Guidelines for Model Criteria Sets, Sample Peer Review Form, Sample data from Pilot Applications of Guidelines, and Glossary of Terms Used.

Part III titled PEER REVIEW AND CHILD PSYCHIATRY contains sections of Special Considerations, Legal Rights of Children, Issue of Confidentiality, Conclusions, References, and Appendices on Model Screen Criteria Format for Intermediate Care, for Acute Care in a Short Stay Facilities, and for Partial Hospitalization, Outpatient Diagnostic Evaluation Procedures, and Outpatient Treatment for Children and Adolescents.

Thought disorder, hallucinations and hostility managed
Sam T. is now asymptomatic with no sexual dysfunction or other major side effects.*

LOXITANE® Loxapine Succinate

Permits rapid management of Sam's hostility and excited behavior

Thirty-six year old salad maker, claiming to be the "Wild Man of the West" was brought to the hospital by his kitchen supervisor. History revealed prior psychiatric hospitalizations and therapies including psychotropic drugs. Hypertension was noted as a complication of earlier treatment with anti-psychotic drugs. Diagnosis: chronic schizophrenia, acute exacerbation. He responded promptly to LOXITANE® C Loxapine HCl Concentrate 50 mg stat, followed by LOXITANE® Loxapine Succinate capsules 30 mg t.i.d.

Permits aggressive titration for rapid establishment of optimal management of Sam's thought disorder and hallucinations

During first week, LOXITANE dosage increased to 50 mg q.i.d. Significant improvement in thought disorder noted by third week. Auditory hallucinations and delusions much less frequent. Patient calmer and more cooperative.

Permits sustained symptom management with minimal risk of serious adverse effects, such as sexual dysfunction

Patient revealed that while on outpatient status, he failed to take his previously prescribed antipsychotic for a ten-month period after he met and married his girlfriend. He stated the drug "didn't let me be a man." No sexual dysfunction reported with LOXITANE.

Side effects are usually mild, transitory and easily managed

Patient felt anxious because his "heart was beating so fast," and he "could not sit still." Increased pulse rate and restlessness subsided following decrease of LOXITANE to 20 mg q.i.d.

Consistence in schizophrenic symptom management and tolerance promotes patient compliance

All admitting symptomatology under control by the fourth week. By the sixth week, he was anxious to return home. Stated "this medicine doesn't make me feel drowsy like the other did." Discharged by the eighth week. He returned to work fully managed on LOXITANE 20 mg t.i.d., and free from recurrence of previously reported side effects.

*Painful ejaculation and urine containing sperm have not been reported. Endocrine disturbances such as galactorrhea and menstrual irregularities have only been rarely reported. Other sexual side effects infrequently reported. Although not reported to date, possibility of hepatic, renal, ocular, or phototoxicity cannot be ruled out at this time. Transient liver enzyme changes not definitely related to LOXITANE have been reported. Not an actual patient, but a simulation to illustrate the action of LOXITANE as reported in clinical studies.

See LOXITANE prescribing information on following page for indications, warnings and precautions and for more detailed information concerning side effects.

Recommended Daily Dosage

	MILD	MODERATE	SEVERE
Initial Dosage	10 mg b.i.d.	10 mg t.i.d or q.i.d.	25 mg b.i.d.
First 7 to 10 days	Increase dosage until psychotic symptoms are controlled. Dosage should not exceed 250 mg/day. Usual dosage during titration: 50 to 150 mg/day.		
Maintenance Dosage	Adjust to lowest effective level. Usual maintenance dosage: 60 to 100 mg/day. Many patients are controlled with dosages as low as 20 to 60 mg/day.		

Brief Summary
LOXITANE® Loxapine Succinate Capsules
LOXITANE® C Loxapine Hydrochloride Oral Concentrate
INDICATIONS: Manifestations of schizophrenia.
CONTRAINDICATIONS: Comatose or severely depressed states; hypersensitivity to the drug.
WARNINGS: Safe use during pregnancy or lactation has not been established; weigh potential benefits to possible hazards. Not recommended for use in children under 16. May impair mental and/or physical abilities especially during early therapy; warn ambulatory patients about activities requiring alertness and concomitant use of alcohol or other CNS depressants. Not recommended for management of behavioral complications in mentally retarded patients.
PRECAUTIONS: Use with extreme caution in patients with a history of convulsive disorders; use with caution in patients with cardiovascular disease or in those with glaucoma or a tendency to urinary retention particularly when on concomitant anticholinergic medication. Loxapine has an antiemetic effect in animals which might occur in man masking signs of overdosage of toxic drugs and obscuring intestinal obstruction or brain tumor. Since possible ocular toxicity cannot be excluded, observe carefully for pigmentary retinopathy and lenticular pigmentation.
ADVERSE REACTIONS: CNS effects, other than extrapyramidal, infrequent. Mild drowsiness may occur at beginning of therapy or upon dosage increase, usually subsides with continued therapy. Sedation, dizziness, faintness, staggering gait, muscle twitching, weakness and confusional states have been reported. Extrapyramidal reactions often occur early in treatment manifested by Parkinson-like symptoms (tremor, rigidity, excessive salivation, masked facies, akathisia) controllable by dosage reduction or antiparkinson drugs at usual dosages. Dystonic and dyskinetic reactions, while less frequently occurring, may be more severe, requiring dosage reduction or temporary withdrawal plus appropriate counteractive drugs. Persistent Tardive Dyskinesia may appear during prolonged therapy or following discontinuance, the risk greater in the elderly, especially females, on high dosage. Symptoms, persistent and in some patients apparently irreversible, are characterized by rhythmical involuntary movement of the tongue, face, mouth and jaw sometimes accompanied by involuntary movement of extremities. Since there is no known effective treatment, discontinue all antipsychotic drugs if symptoms appear. Reinstitution of treatment, increased dosage, or switching to another agent may mask syndrome. The syndrome may not develop if medication is stopped when fine vermicular movements of the tongue first appear. Cardiovascular Effects: Tachycardia, hypotension, hypertension, lightheadedness and syncope. ECG changes, not known to be related to loxapine use, have been reported. Skin: Dermatitis, edema of face, pruritus, seborrhea. Possible photosensitivity and/or phototoxicity; skin rashes of unknown etiology seen in a few patients in hot summer months. Anticholinergic: Dry mouth, nasal congestion, constipation, blurred vision (more likely to occur with concomitant use of antiparkinson agents). Other: Nausea, vomiting, weight gain or loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, polydipsia. Rarely, galactorrhea and menstrual irregularity of unknown etiology.

The patient with clinically significant depression

He's getting better...

and ELAVIL®

(AMITRIPTYLINE HCl | MSD)

is helping

Helping with symptom relief

ELAVIL usually relieves a broad range of symptoms associated with depression, including sleep disturbance, one of the most frequently observed in the "constellation of symptoms," and usually the first symptom to respond to therapy.

And, the anxiety-reducing sedative component extends the drug's clinical value when depression is accompanied by symptoms of anxiety. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol.

Helping with convenient dosage regimens

ELAVIL offers a variety of convenient dosage regimens. A once-daily bedtime regimen may be an effective prescribing option, particularly when taken by a depressed patient experiencing sleep disturbance. ELAVIL can also be prescribed in divided daily doses. Prescriptions should be written for the smallest amount feasible.

Providing a wide range of tablet strengths

ELAVIL offers six color-coded tablets, available in the following strengths: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg. And for special circumstances, an injectable form is available. Injection ELAVIL is supplied in 10-ml vials, 10 mg/ml.

ABLETS: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg
NJECTION: 10 mg per ml

Elavil®

(AMITRIPTYLINE HCl | MSD)

helping relieve the symptoms of clinically significant depression

MSD
MERCK SHARP & DOHME

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.

When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

JBEL26 (116)

The American Psychiatric Association announces publication of two volumes reporting the Conference on Education of Psychiatrists

held at Lake of the Ozarks, Missouri, June 9-15, 1975. Organized by the A.P.A. in cooperation with the American Academy of Child Psychiatry, the American Association of Chairmen of Departments of Psychiatry, and the American Association of Directors of Psychiatric Residency Training.

1. PSYCHIATRIC EDUCATION: PROLOGUE TO THE 1980's, Library Bound, 544 pages, $15.00.

This is a substantive, highly readable, report of the Conference, written by Anne H. Rosenfeld with an Editorial Board comprising: Ewald W. Busse, M.D., Chairperson of the Conference, Walter E. Barton, M.D., Bernard Holland, M.D., Donna Norris, M.D., Melvin Sabshin, M.D., Jeanne Spurlock, M.D., and Robert L. Robinson, M.A. (Staff Consultant).

The volume contains ten chapters covering the topical structure of the Conference: Goals and Values; Competence, Evaluation, and Quality Control; The Resident; Faculty; Educational Methods: Means in the Service of Ends; The Program Environment; Research; The Economics of Residency Training; Psychiatry in Its Social Context; and Retrospect and Prospect. It also contains nine appendices describing the organization of the Conference and its participants, together with selected model programs and related informational materials of value.

2. THE WORKING PAPERS OF THE 1975 CONFERENCE ON EDUCATION OF PSYCHIATRISTS Paper bound, 432 pages, $12.50.

Sixty two leading psychiatric educators served on seven preparatory commissions, one for each of seven topic areas, and prepared advance working papers as a basis for Conference deliberations. The topics and Commission Chairpersons were: Social Issues and Needs (James N. Sussex, M.D.); Goals and Objectives (Morton F. Reiser, M.D.); The Resident (David R. Hawkins, M.D.); Content, Methodology, Faculty and Environment (Milton Greenblatt, M.D.); Research (Daniel X. Freedman, M.D.); Economics (Herzl Spiro, M.D.); Evaluation and Quality Control (Eric Pfeiffer, M.D.). The Chairpersons, together with the Conference Chairperson, served as the Editorial Board for this volume.

Papers commenting on the reports of the commissions, published here for the first time, were presented at the Conference by Melvin Sabshin, M.D., Eugene B. Brody, M.D., Jeanne Spurlock, M.D., Jack R. Ewalt, M.D., Robert J. Stoller, M.D., James R. Comer, M.D., and Bernard Holland, M.D.

Tranxene® CIV

(CLORAZEPATE DIPOTASSIUM) 4306CB

CAPSULES,
SINGLE DOSE TABLETS
Brief Summary

ACTIONS — Pharmacologically, clorazepate dipotassium has the characteristics of the benzodiazepines. It has depressant effects on the central nervous system. The primary metabolite, nordiazepam, quickly appears in the blood stream. The serum half-life is about 2 days. The drug is metabolized in the liver and excreted primarily in the urine. (See CLINICAL PHARMACOLOGY section.)

INDICATIONS — TRANXENE is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

TRANXENE is indicated for the symptomatic relief of acute alcohol withdrawal.

The effectiveness of TRANXENE in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

CONTRAINDICATIONS — TRANXENE is contraindicated in patients with a known hypersensitivity to the drug, and in those with acute narrow angle glaucoma.

WARNINGS — TRANXENE is not recommended for use in depressive neuroses or in psychotic reactions.

Patients on TRANXENE should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles.

Since TRANXENE has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, and cautioned that the effects of alcohol may be increased.

Because of the lack of sufficient clinical experience, TRANXENE is not recommended for use in patients less than 18 years of age.

Physical and Psychological Dependence:

Withdrawal symptoms (similar in character to those noted with barbiturates and alcohol) have occurred following abrupt discontinuance of clorazepate. Symptoms of nervousness, insomnia, irritability, diarrhea, muscle aches and memory impairment have followed abrupt withdrawal after long-term use of high dosage.

Caution should be observed in patients who are considered to have a psychological potential for drug dependence.

Evidence of drug dependence has been observed in dogs and rabbits which was characterized by convulsive seizures when the drug was abruptly withdrawn or the dose was reduced; the syndrome in dogs could be abolished by administration of clorazepate.

Usage in Pregnancy:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. TRANXENE, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.

Usage during Lactation:

TRANXENE should not be given to nursing mothers since it has been reported that nordiazepam is excreted in human breast milk.

PRECAUTIONS — In those patients in which a degree of depression accompanies the anxiety, suicidal tendencies may be present and protective measures may be required. The least amount of drug that is feasible should be available to the patient.

Patients on TRANXENE for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

ADVERSE REACTIONS — The side effect most frequently reported was drowsiness. Less commonly reported (in descending order of occurrence) were: dizziness, various gastrointestinal complaints, nervousness, blurred vision, dry mouth, headache, and mental confusion. Other side effects included insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression and slurred speech.

There have been reports of abnormal liver and kidney function tests and of decrease in hematocrit.

Decrease in systolic blood pressure has been observed.

DOSAGE AND ADMINISTRATION

For the symptomatic relief of anxiety:

TRANXENE is administered orally. The capsules may be given in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 15 to 60 mg. daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a daily dose of 7.5 to 15 mg.

TRANXENE capsules may also be administered as a single dose daily at bedtime; the recommended initial dose is 15 mg. After the initial dose, the response of the patient may require adjustment of subsequent dosage. Lower doses may be indicated in the elderly patient. Drowsiness may occur at the initiation of treatment and with dosage increment.

TRANXENE-SD tablets (22.5 mg.) may be administered as a single dose every 24 hours. This tablet is intended as an alternate dosage form for the convenience of patients stabilized on a dose of 7.5 mg. capsules three times a day. TRANXENE-SD tablets should not be used to initiate therapy.

TRANXENE-SD HALF STRENGTH tablets (11.25 mg.) may be administered as a single dose every 24 hours.

For the symptomatic relief of acute alcohol withdrawal:

Recommended schedule: 1st 24 hours, 30 mg. TRANXENE initially, followed by 30 to 60 mg. in divided doses; 2nd 24 hours, 45 to 90 mg. in divided doses; 3rd 24 hours, 22.5 to 45 mg. in divided doses; 4th day, 15 to 30 mg. in divided doses. Thereafter gradually reduce to 7.5 to 15 mg. daily, and discontinue as soon as condition is stable. Maximum daily dose is 90 mg. Avoid excessive reductions in total drug on successive days.

DRUG INTERACTIONS — If TRANXENE is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. Animal experience indicates that TRANXENE prolongs the sleeping time after hexobarbital or after ethyl alcohol, increases the inhibitory effects of chlorpromazine, but does not exhibit monoamine oxidase inhibition. Clinical studies have shown increased sedation with concurrent hypnotic medications. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If TRANXENE is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

MANAGEMENT OF OVERDOSAGE — Overdosage is usually manifested by varying degrees of CNS depression ranging from slight sedation to coma. As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

There are no specific antidotes for the benzodiazepines. The treatment of overdosage should consist of the general measures employed in the management of overdosage of any CNS depressant. Gastric evacuation either by the induction of emesis, lavage, or both, should be performed immediately. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though rarely reported, may occur with large overdoses. In such cases the use of agents such as Levophed® (levarterenol) or Aramine® (metaraminol) should be considered.

While reports indicate that individuals have survived overdoses of TRANXENE (clorazepate dipotassium) as high as 450 to 675 mg., these doses are not necessarily an accurate indication of the amount of drug absorbed since the time interval between ingestion and the institution of treatment was not always known. Sedation in varying degrees was the most common physiological manifestation of TRANXENE overdosage. Deep coma when it occurred was usually associated with the ingestion of other drugs in addition to TRANXENE.

CLINICAL PHARMACOLOGY — Studies in healthy men have shown that TRANXENE has depressant effects on the central nervous system. Prolonged administration of single daily doses as high as 120 mg. was without toxic effects. Abrupt cessation of high doses was followed in some patients by nervousness, insomnia, irritability, diarrhea, muscle aches, or memory impairment.

Absorption — Excretion:

After oral administration of TRANXENE, there is essentially no circulating parent drug. Nordiazepam, its primary metabolite, quickly appears in the blood stream. In 2 volunteers given 15 mg. (50 μC) of ^{14}C-TRANXENE, about 80% was recovered in the urine and feces within 10 days. Excretion was primarily in the urine with about 1% excreted per day on day 10.

HOW SUPPLIED — TRANXENE (clorazepate dipotassium) is supplied as capsules in three dosage strengths:

3.75 mg. capsules (gray with white cap) in bottles of 100 (NDC 0074-3417-13) and 500 (NDC 0074-3417-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3417-11).

7.5 mg. capsules (gray with maroon cap) in bottles of 30 (NDC 0074-3418-30), 100 (NDC 0074-3418-13) and 500 (NDC 0074-3418-53). Also available in ABBO-PAC unit dose packages of 100 capsules (NDC 0074-3418-11).

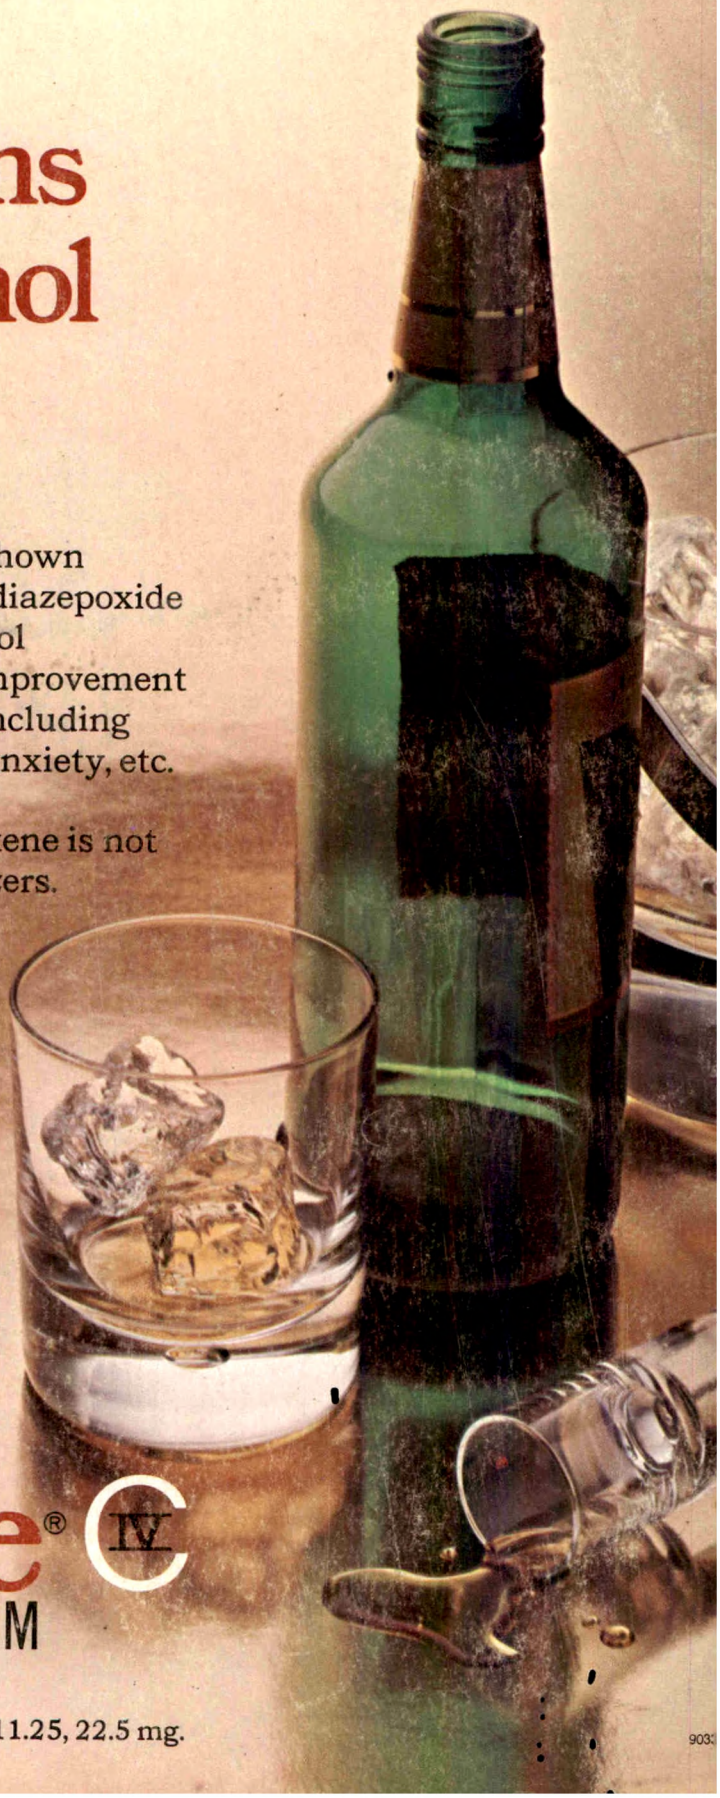
15 mg. capsules (all gray) in bottles of 100 (NDC 0074-3419-13) and 500 (NDC 0074-3419-53). Also available in ABBO-PAC unit dose packages of 100 capsules (NDC 0074-3419-11).

TRANXENE-SD single dose tablets are supplied in two dosage strengths:

TRANXENE-SD 22.5 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-2997-13).

TRANXENE-SD HALF STRENGTH 11.25 mg. tablets (blue-colored) in bottles of 30 (NDC 0074-2699-30) and 100 (NDC 0074-2699-13).

To help limit the risk of complications during alcohol withdrawal



Effective Tranxene has been shown therapeutically equivalent to chlordiazepoxide in easing the distress of acute alcohol withdrawal. Rapid symptomatic improvement has been demonstrated in studies including tremors, agitation, hallucinations, anxiety, etc.

Not widely known Tranxene is not as widely known as some tranquilizers. Thus it will be unfamiliar to most patients, as well as to paramedical alcoholic support organizations.

Simple to administer
The Tranxene regimen is easy to manage. A simple tapering schedule is recommended, with decreasing amounts over five days. Discontinue as soon as the patient's condition is stable.

OFFICIAL JOURNAL OF THE AMERICAN PSYCHIATRIC ASSOCIATION

BACK TO WORK
PONDER GOEMBEL

THORAZINE®

brand of

CHLORPROMAZINE

Tablets:
50 and 100 mg
of the HCl

Back to work. She went into the hospital with a psychiatric emergency but left more like herself—delusions, hallucinations, and other psychotic target symptoms effectively managed with 'Thorazine'. And 'Thorazine' maintenance can help keep her out of the hospital in the future.

From initial psychiatric emergency through maintenance treatment, 'Thorazine' offers effective antipsychotic therapy with 18 convenient dosage forms and strengths. This means you can precisely tailor dosage to the individual patient's needs—increasing or decreasing as the situation demands.

'Thorazine'. The most widely tested and highly flexible antipsychotic available today.

Helps return psychotic patients to reality

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings: The possibility of extrapyramidal reactions from 'Thorazine' may confuse the diagnosis of Reye's syndrome or other encephalopathy. Therefore, avoid use in children or adolescents with suspected Reye's syndrome.

Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery) especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

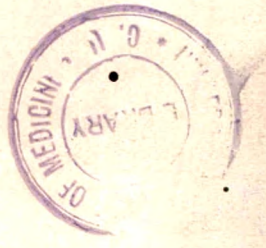
Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or obscure diagnosis of conditions such as intestinal obstruction, brain tumor, and Reye's syndrome (see Warnings). Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudoparkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.

NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; Single Unit Packages of 100 (intended for institutional use only).



Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only).

Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg.

Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

Meyerson, M.D., Kenneth Minkoff, M.D., Samuel Muszynski, M.S.W., Lucy D. Ozarin, M.D., Gordon L. Paul, Ph.D., Ronald Peterson, Steven S. Sharfstein, M.D., Judith Clark Turner, Jane Bloom Yohalem, J.D.

This 277-page Report of the Conference, sponsored by APA and President Carter's Commission on Mental Health, identifies the chronic mental patient population, spells out where they are and what their needs and rights are. It specifies what programs work and what programs do not work in meeting the needs of these patients. It elaborates on the obstacles to implementing effective programs and the economic issues involved. It delineates the pros and cons of case management and specifies responsibility for coordinating, implementing, and monitoring services to chronic mental patients.

Finally, it proposes a *Call to Action* which opens with this statement: "There is no more urgent concern than the needs of the chronic mentally ill who suffer from severe, persistent, or recurrent mental illnesses with residual social and vocational disabilities. As a result of the deinstitutionalization programs of the past decade and the continuing growth of high risk populations that generate chronically ill, the problems associated with the care of these patients constitute a national crisis."

Since the Conference, the APA Assembly and the Board of Trustees have both approved the "Call to Action" which calls upon the APA to take the lead in undertaking programs to elevate the prestige and value of work with chronic mentally ill patients.

It follows that all APA members should be thoroughly versed in the current problems of this chronic patient population. This is best accomplished by reading this Conference Report now available from APA Publications Services at $11.00 a copy.

THE AMERICAN JOURNAL OF PSYCHIATRY

(ISSN 0002-953X)

OFFICIAL JOURNAL OF THE
AMERICAN PSYCHIATRIC ASSOCIATION

The American Journal of Psychiatry is published by the American Psychiatric Association 13 times a year (monthly, plus a second issue in April devoted in 1979 to depression and alcoholism). Editorial office: 1700 Eighteenth Street, N.W., Washington, D.C. 20009; telephone (202) 797-4918.

Subscriptions: U.S. $27.00 per year, Canada and foreign $35.00; single issues: U.S. $3.50, Canada and foreign $4.25.

Business communications and changes of address from APA members should be directed to the Division of Membership Services and Studies. Communications from nonmember subscribers should be directed to the Circulation Department, American Psychiatric Association, 1700 Eighteenth Street, N.W., Washington, D.C. 20009.

Advertising representatives: Steven K. Herlitz, Inc., 850 Third Avenue, New York, N.Y. 10022. Type set by Byrd PrePress, 5408 Port Royal Road, Springfield, Va. 22151. Printed by Dartmouth Printing Co., 69 Lyme Road, Hanover, N.H. 03755.

Second class postage paid at Washington, D.C., and additional mailing offices.

Indexed in *Abstracts for Social Workers, Biological Abstracts, Chemical Abstracts, Cumulative Index to Nursing Literature, Excerpta Medica, Hospital Literature Index, Index Medicus, International Nursing Index, Nutrition Abstracts, Psychological Abstracts,* and *Social Sciences Index.*

Information for Contributors

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material, have not been published previously, and are not being considered for publication elsewhere. Papers with multiple authors are reviewed with the assumption that all authors have approved them.

Copyright

The *Journal* requires express transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. All submissions must be accompanied by a cover letter *signed by all authors* and using the following wording:

In consideration of the *American Journal of Psychiatry*'s taking action in reviewing and editing my submission [include title here] the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the American Psychiatric Association in the event that such work is published by the American Psychiatric Association.

Work done as part of an individual's duties as a federal employee is in the public domain. The cover letter in such cases should contain the following wording and should be signed by all authors:

The work described in [include title here] was done as part of my (our) employment with the federal government and is therefore in the public domain.

In addition, authors must obtain letters of permission from publishers for use of extensive quotations (more than 500 words) and of tables and figures that originally appeared elsewhere.

Patient Anonymity

Ethical as well as legal considerations require careful attention to the protection of a patient's anonymity in case reports and elsewhere. Identifying information such as names, initials, hospital numbers, and dates must be avoided. In addition, authors should disguise identifying information about a patient's characteristics and personal history.

Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained.

Review Process

Papers are reviewed by at least two experts to determine the originality, validity, and significance of content and conclusions. Authors will usually be advised within 2–3 months of the decision on their paper, although delays are sometimes unavoidable. Reviewers' comments will be returned with rejected manuscripts if they are judged to be useful to the authors. All reviewers remain anonymous.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. All correspondence will be sent to the first-named author unless otherwise specified. Papers that are not accompanied by the appropriate cover letter, including the copyright transfer statement, will not be reviewed until such a statement is received.

Authors will be notified as soon as possible of the receipt of their paper; at this time, the paper will be assigned a number that must be included in all further correspondence. It is imperative that authors of papers under consideration notify the *Journal* of changes of address.

Annual Meeting Papers

The *Journal* has first refusal rights for numbered papers accepted for presentation at the Association's annual meetings. Authors of annual meeting papers should follow instructions they will receive in a letter from the Editor before the meeting. Annual meeting papers may be submitted for review before the meeting only if they are in *final form*, i.e., are ready for review. Authors must *not* submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. These papers are subject to the same peer review criteria as other submissions, and not all papers can be published in the *Journal*. Authors who wish to submit their papers elsewhere must secure permission from the Editor. The *Journal* will assign its own number to each paper received for review; this number must appear in any further communications about the paper. The copyright transfer statement described above must accompany annual meeting papers submitted for review.

Length

The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles—3,800 words or the equivalent, including references, tables, and figures (about 15 manuscript pages). Brief Communications—2,500 words or equivalent (about 10 manuscript pages). Clinical and Research Reports—1,000 words, 10 references, 1 table (no figures can be used in this section). Letters to the Editor—500 words, 5 references. The number of words, tables, and figures should be noted on the title page.

TYPES OF ARTICLES

Overviews

Overview articles attempt to bring together important relevant information on a topic of general interest to psychiatry. They are usually written at the invitation of the Editor; authors who have ideas for overview articles are advised to check with the Editor to ensure that a similar work is not in preparation. Overviews should not exceed 25 double-spaced pages (about 7,500 words) and should have no more than 100 references. All overviews, including those written by invitation, are given the same peer review received by other papers.

Regular Articles and Brief Communications

The primary difference between these two types of papers is length. The "brief communication" designation does not imply less sophisticated or complete work: it merely means that the content can be expressed within the upper limit of 2,500 words. There is no difference in the review procedure or scheduling of these articles. Authors who submit unnecessarily long articles with redundancies and loose writing style will be asked to shorten them, which can delay publication. Authors should choose their words carefully, avoiding lengthy introductions containing material that is common knowledge, summaries that merely repeat the results, unnecessary tables, figures or references, etc. Single case reports will not be accepted as regular articles or Brief Communications; these papers should be submitted as Clinical and Research Reports.

Clinical and Research Reports

This section contains very brief articles (maximum of 1,000 words, 10 references, 1 table, and *no figures*) reporting new research findings, including preliminary data from pilot

studies, and case reports that 1) describe new syndromes, 2) cast a new light on established ones, 3) indicate a new therapeutic procedure of potential value, or 4) describe adverse effects or previously unreported complications of drugs or therapeutic interventions. Because of the stringent criteria for this section, authors can expect more rapid publication than is possible in other sections. Submitted papers that substantially exceed the stated maximum length or contain figures will be returned to the author unreviewed.

Prompt Publication Policy

Articles submitted for prompt publication can be of either regular or Brief Communication length (a "prompt publication policy" is automatically in effect for Clinical and Research Reports). These papers are given priority in scheduling; however, authors should be aware that the minimum publication time is four months. Prompt publication papers must meet stringent criteria of originality and be of major, immediate importance to the field. Authors must state their reasons for wanting rapid review in a cover letter to the Editor. It is important to think carefully about the nature of the paper before requesting prompt publication; a paper may be delayed if it is submitted inappropriately.

Other Sections

Letters to the Editor. Brief letters (maximum of 500 words and 5 references) will be considered if they include the notation "for publication" in the upper right corner. Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. The *Journal* is unable to notify authors of receipt of letters or to return those not published. All letters are subject to editing. Letters must be typed *double-spaced* throughout on letter-size bond paper; two copies are required. Letters that are not typed appropriately or do not conform to *Journal* reference style will be returned to the author for revision.

Book Reviews. Books for review or listing may be sent directly to the Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. Book reviews are usually solicited by the editor. Authors interested in reviewing a particular book are urged to contact the editorial office to see if the Editor wishes the book to be reviewed and to ascertain whether it has been previously assigned to another reviewer. Reviews are usually less than 500 words long, seldom contain references, and will be edited.

TYPING AND ARRANGING THE PAPER

All manuscripts must be typed in upper- and lowercase on one side only of 22 × 28 cm (8½ × 11 inches) *nonerasable* bond paper. All parts of the manuscript, including case reports, quotations, references, and tables, must be double-spaced throughout. All 4 margins must be 3¾ cm (1½ inches). The manuscript should be arranged in the following order, with each numbered item beginning a new page: 1) title page, 2) précis, 3) text, 4) references, 5) tables, 6) footnotes to text, and 7) figure captions. All pages must be numbered, with the title page as number 1. Please consult the following section on *Journal* style specifications for criteria for each part of the paper.

STYLE SPECIFICATIONS

Title Page

Title. The title should be informative but as brief as possible. Headline style (declarative sentences) should be avoided. Abbreviations and acronyms are rarely used.

By-line. Authors named in the by-line should be limited to principal researchers and/or writers; collaborators can be acknowledged in a footnote. Please include degrees (other than honorary or undergraduate) after the authors' names.

Previous presentation. If the paper has been presented orally, please give the name of the meeting, the place, and inclusive dates.

Author affiliations. The authors' position titles and affiliations should be given in a paragraph using complete sentences. A full address is necessary only for the author who is to receive reprint requests.

Acknowledgments. Acknowledgments should be in a separate paragraph on the title page. Grant support should include the full name of the granting agency as well as the grant number. Individual acknowledgments should be as brief as possible. Acknowledgments of companies that supplied drugs are used only in the case of experimental drugs or those unavailable in this country.

Other requirements. The number of words, tables, and figures should appear in the upper right corner and a phone number for the corresponding author in the lower right.

Précis

The précis should be up to 100 words for regular articles and Brief Communications (no précis is used in the Clinical and Research Reports section). The précis should be a single paragraph using complete, connected sentences, active verbs, and the third person. In most cases, the précis replaces a summary.

Text

Headings and subheadings should be inserted at reasonable intervals in all types of papers. Footnotes to text material should be typed on a separate page at the end of the manuscript. Summaries are rarely desirable, although a final "Comment" or "Conclusions" section may be used. The body of the paper should be written in the active voice and first person where appropriate.

Statistics. Authors should be sure that statistics used are both necessary and appropriate. Statistical tests should be described and a reference citation given if the tests are not generally known. It is not sufficient to say "differences between the groups were significant." In cases of lengthy complicated analyses, the authors may summarize results and indicate that details are available from them on request.

Abbreviations. All abbreviations (other than those for metric units) should be explained the first time they are used. Idiosyncratic abbreviations should be avoided: overuse of abbreviations may hinder rather than facilitate readability.

Drugs. Generic rather than trade names of drugs should be used; trade names may be given parenthetically if necessary.

Units of measurement. All measurements should be in metric units; standard abbreviations are used.

References

References should be restricted to closely pertinent material; a complete review of the literature is rarely desirable. *Accuracy of citation is the author's responsibility.* References should conform exactly to the original spelling, accents, punctuation, etc. Authors should be sure that all references listed have been cited in text; no bibliographies can be used.

References are numbered and listed by their order of appearance in text; the text citation is followed by the appropriate reference number in parentheses. Do *not* arrange the list alphabetically.

Personal communications, unpublished manuscripts, manuscripts submitted but not yet accepted, and similar unpublished items should not appear in the reference list. Such citations may be noted in text or in a footnote. It is the author's responsibility to obtain permission to refer to another individual's unpublished observations. Manuscripts that are actually "in press" may be cited as such in the reference list; the name of the journal must be included.

Type references in the style shown below and on the next page, double-spaced *throughout* (not just a line between

references). List up to three authors; designate one or more authors past the third "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*; journals not indexed there should not be abbreviated.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349-365, 1967
3. Gold PW, Goodwin FK: Urinary free cortisol in depression and mania. Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont, Canada, May 2-6, 1977
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968

Tables

Tables should be self-explanatory and should supplement rather than duplicate text. Authors may be asked to delete tables that present data which could be given succinctly in text or repeat information in the Results section. Tables are generally reserved for data presentation and not used as lists or charts. They should be no wider than 120 typewriter characters, including spaces. Consult recent issues of the *Journal* for table style. Please note that no vertical rules or internal horizontal rules are used. It is usually desirable to give both numbers and percentages where applicable. All units of measurement must be specified within the table. Metric measurements are used in tables and throughout the text. Each table should be identified numerically and include a concise title.

Figures

Figures should be used only for data that cannot be adequately presented in text or tabular form. Figures should be submitted as glossy prints with one photocopy attached to each manuscript copy. The author's name and the title of the paper should appear on a gummed label affixed to the back of each glossy. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Authors are urged to consider carefully the necessity of figures; they may be asked to delete figures that repeat information available in text. It is often advisable to obtain professional assistance in the preparation of figures.

PROCESSING OF ACCEPTED MANUSCRIPTS

Authors will be notified of acceptance of their papers; papers will then be edited and sent to the first-named (or corresponding) author for corrections and answers to editorial queries. No galley proofs are sent to authors, so the edited manuscript should be read with extreme care. Prompt return of edited manuscripts is essential. Authors who expect to be away from their offices for a long period or who change address after notification of acceptance should so inform the *Journal* office.

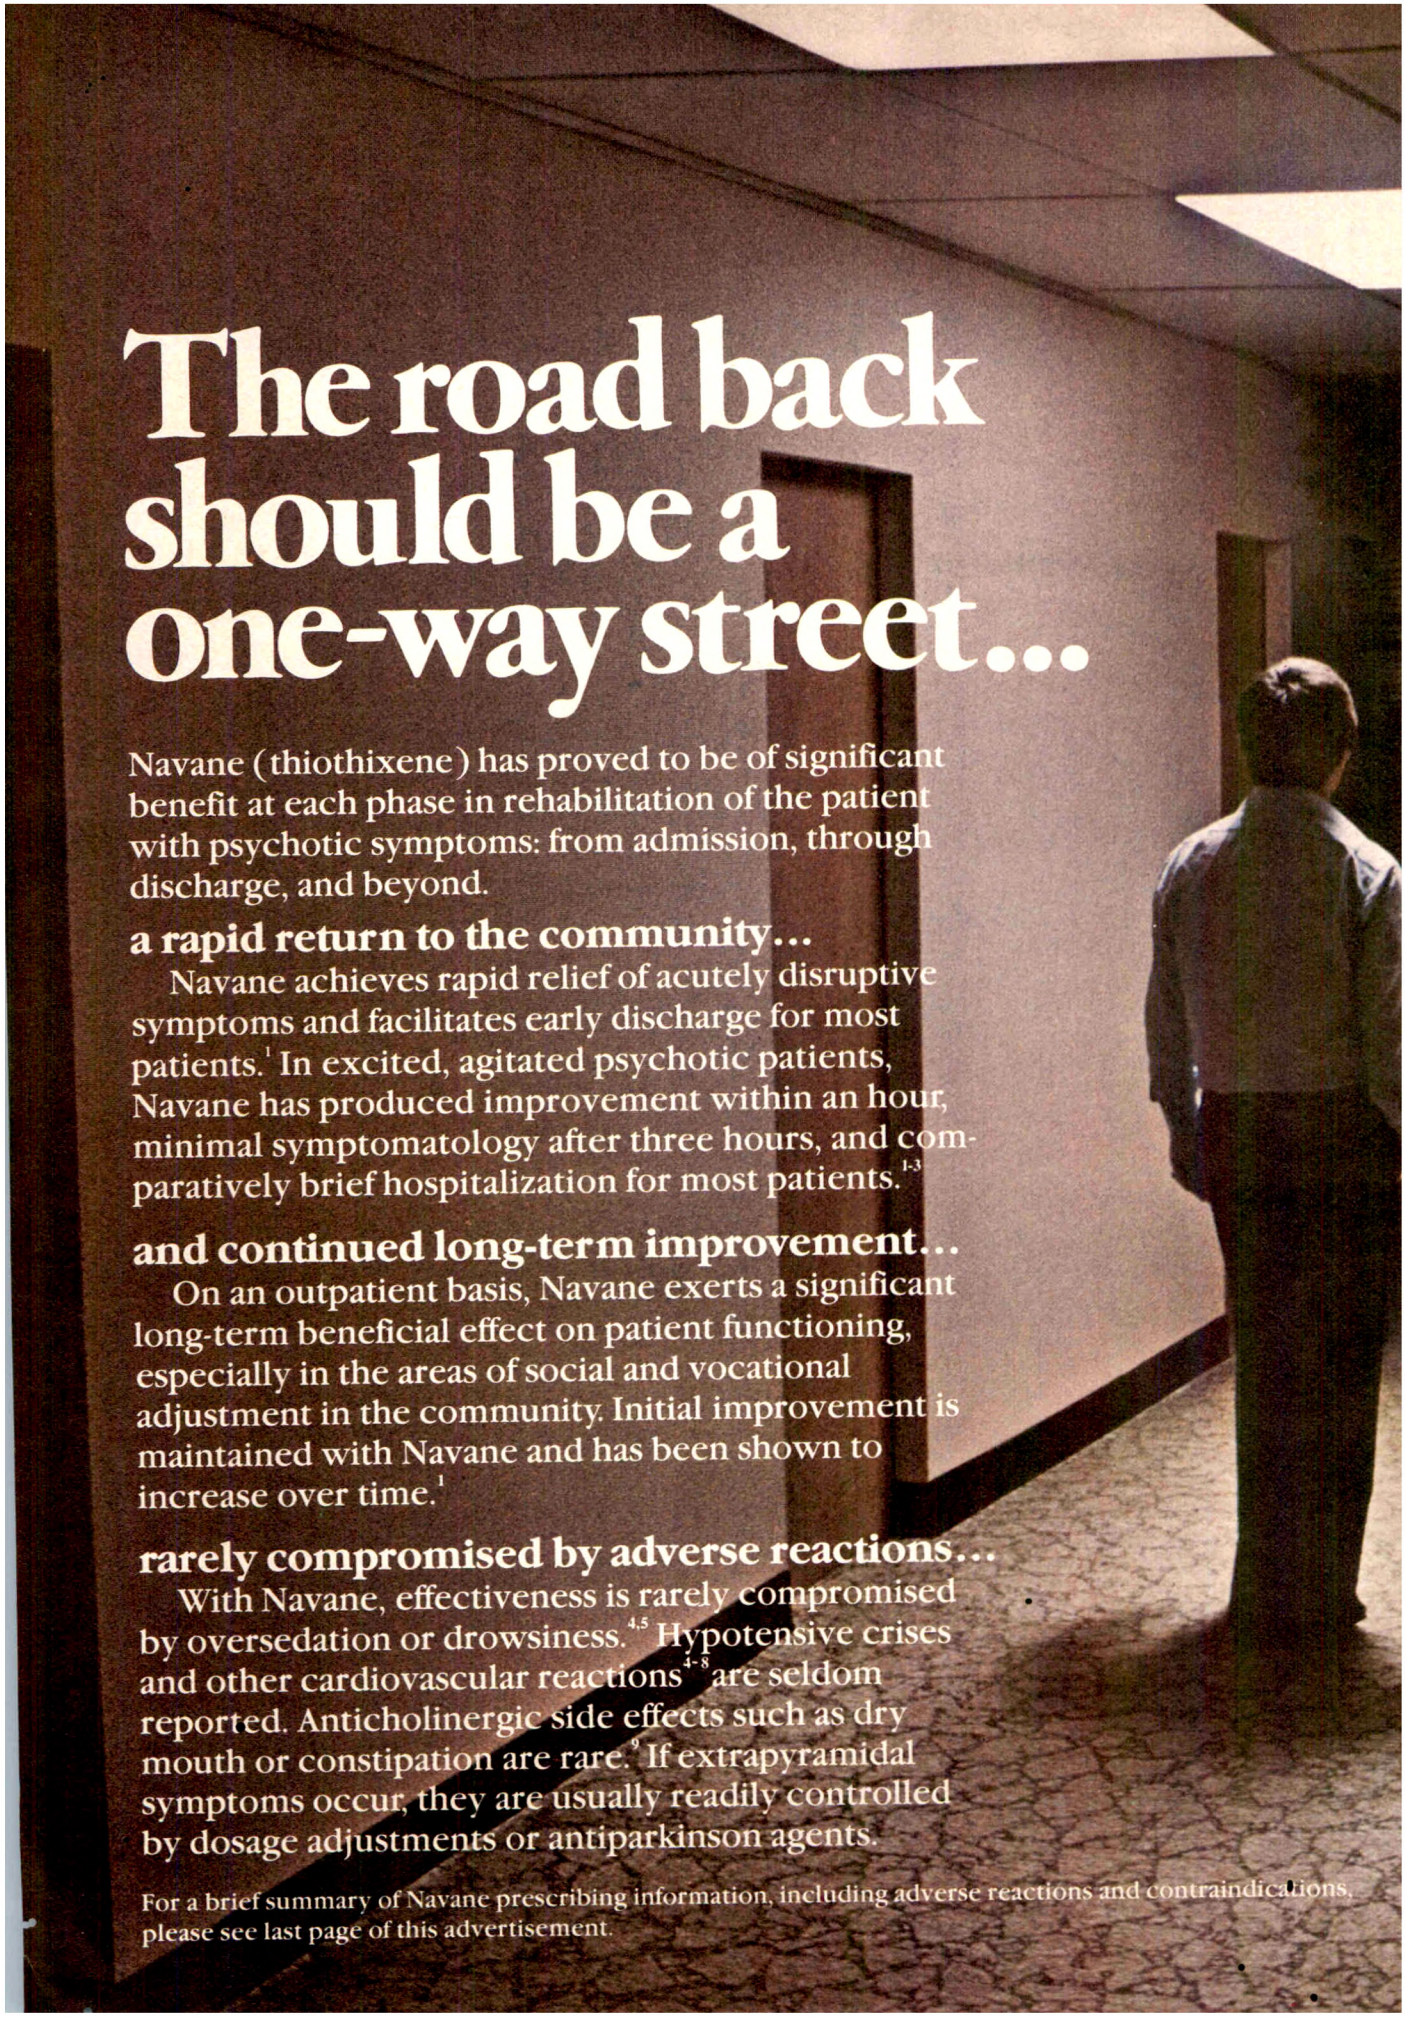
Manuscripts are accepted with the understanding that the Editor has the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style.

PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for such permission, except in cases of nonprofit use for educational purposes or of an author who wishes to reprint his/her own material. Requests will be facilitated if they are accompanied by written permission from the author of the material.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Reprint orders from others should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.



The June 1979 issue of

The American Journal of Psychiatry

will feature

- **"Folk" Criteria for the Diagnosis of Mental Illness in Rural Laos: On Being Insane in Sane Places**

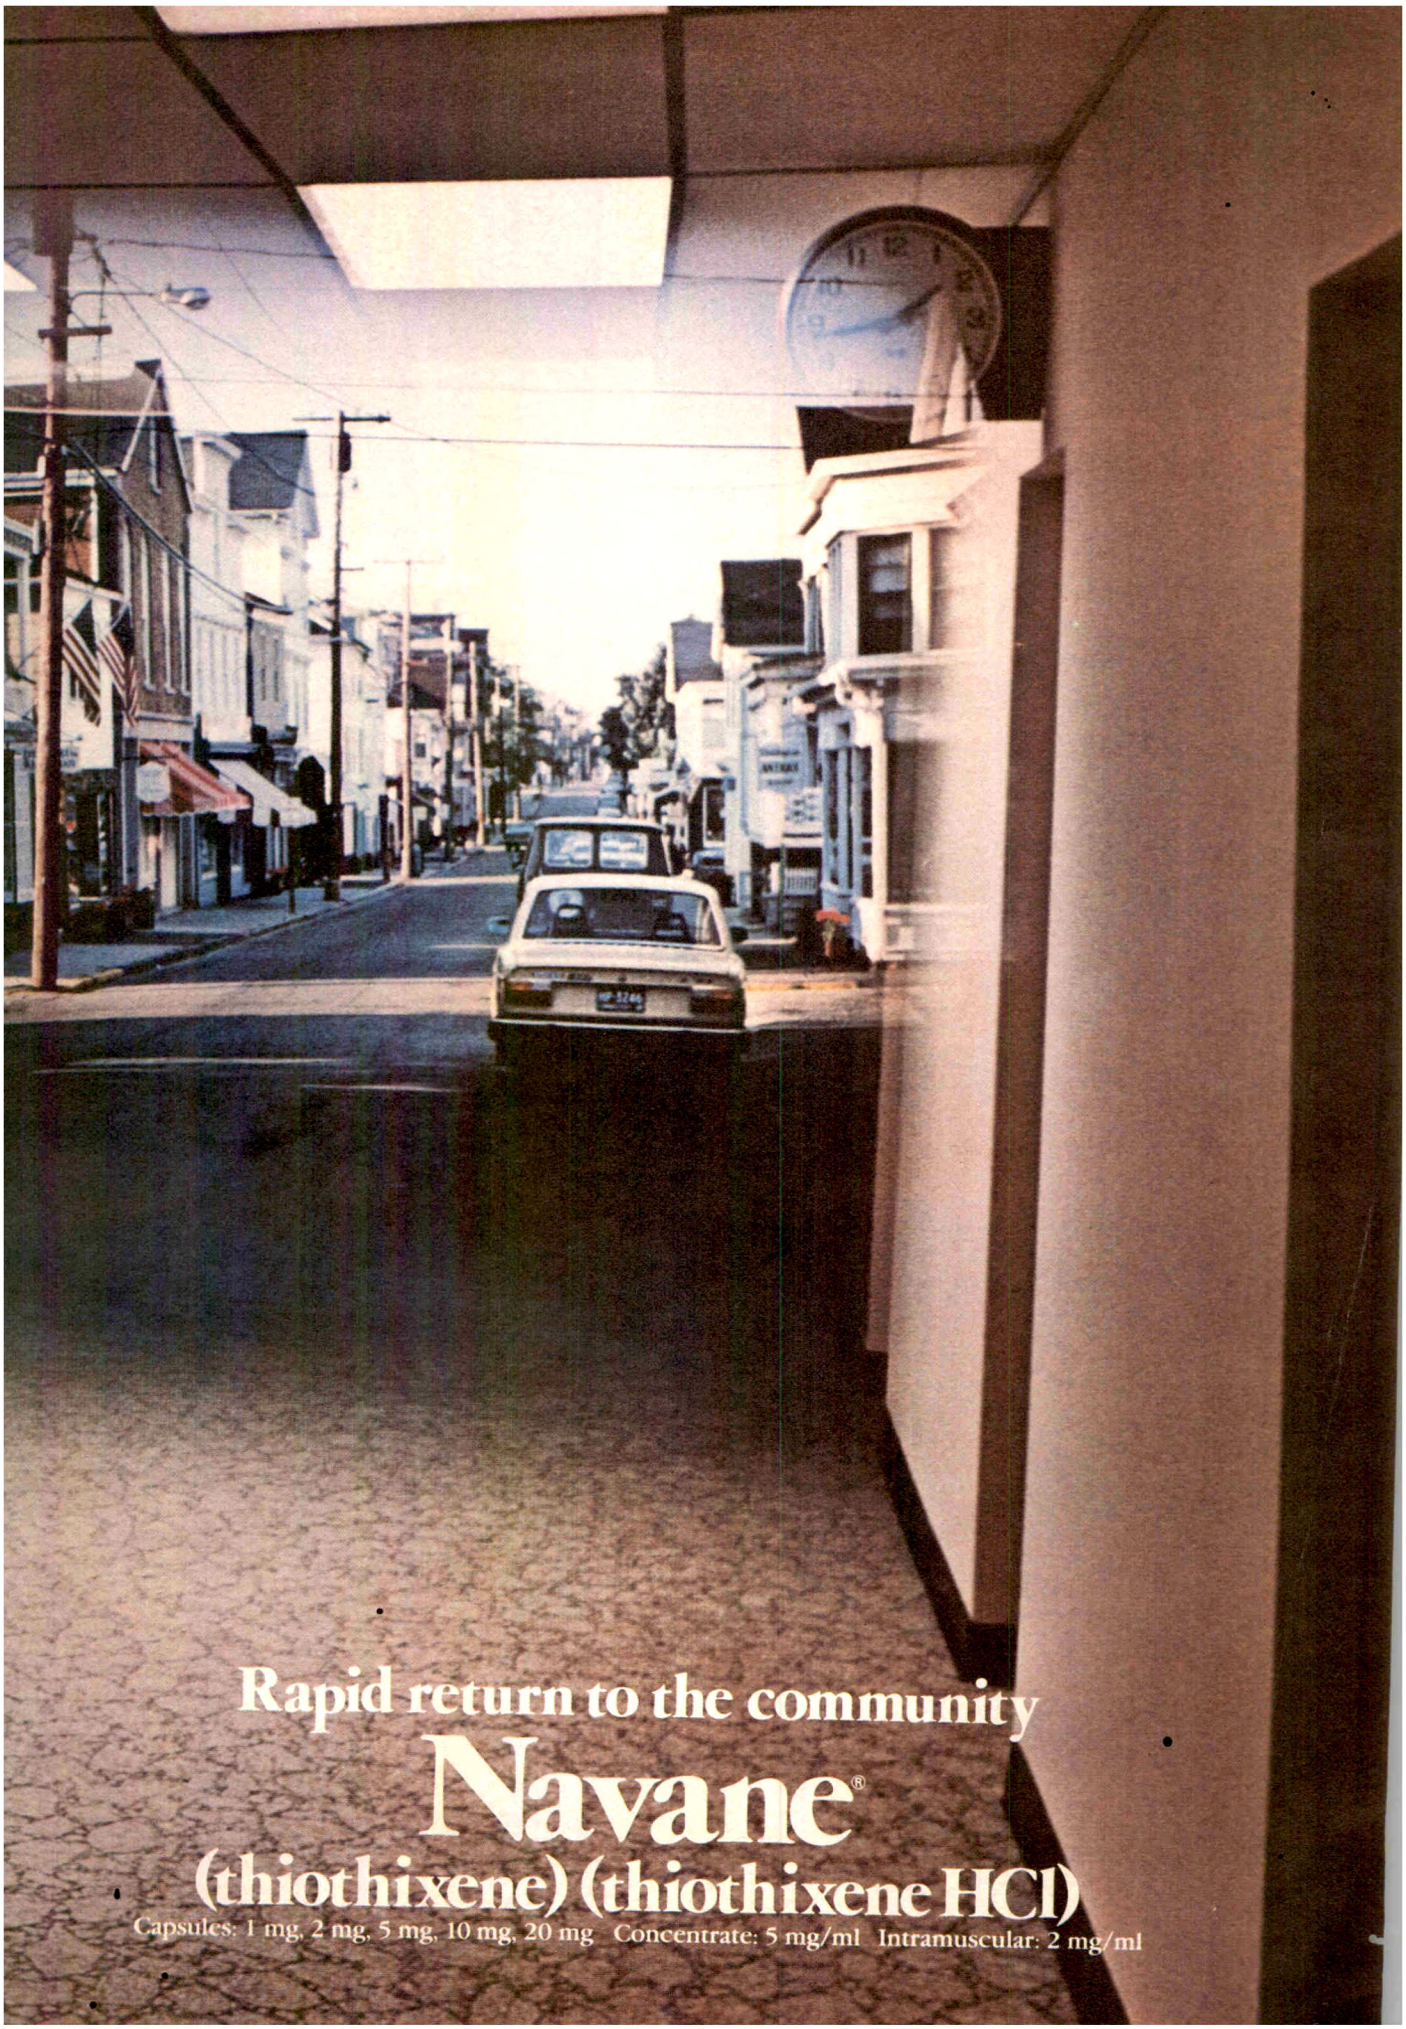
  By Joseph Westermeyer and Ronald Wintrob

The road back should be a one-way street...

Navane (thiothixene) has proved to be of significant benefit at each phase in rehabilitation of the patient with psychotic symptoms: from admission, through discharge, and beyond.

a rapid return to the community...

Navane achieves rapid relief of acutely disruptive symptoms and facilitates early discharge for most patients.[1] In excited, agitated psychotic patients, Navane has produced improvement within an hour, minimal symptomatology after three hours, and comparatively brief hospitalization for most patients.[1-3]



and continued long-term improvement...

On an outpatient basis, Navane exerts a significant long-term beneficial effect on patient functioning, especially in the areas of social and vocational adjustment in the community. Initial improvement is maintained with Navane and has been shown to increase over time.[1]

rarely compromised by adverse reactions...

With Navane, effectiveness is rarely compromised by oversedation or drowsiness.[4,5] Hypotensive crises and other cardiovascular reactions[4-8] are seldom reported. Anticholinergic side effects such as dry mouth or constipation are rare.[9] If extrapyramidal symptoms occur, they are usually readily controlled by dosage adjustments or antiparkinson agents.

For a brief summary of Navane prescribing information, including adverse reactions and contraindications, please see last page of this advertisement.

Rapid return to the community

Navane®

(thiothixene) (thiothixene HCl)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

Rapid return to the community

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

BRIEF SUMMARY OF PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Contraindications. Navane (thiothixene) is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy*– Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration of Navane to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children– The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration– As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane (thiothixene). Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudo-parkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leukocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution–For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane (thiothixene) Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate– In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Stimulants that may cause convulsions (e.g. picrotoxin or pentylenetetrazol) should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg of thiothixene in bottles of 100, 1,000, and unit-dose pack of 100 (10 x 10's). Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100, 500, and unit-dose pack of 100 (10 x 10's).

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg, and in 30 ml (1 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, and 5 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10 vials. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

OUTPATIENT PSYCHIATRY
Diagnosis and Treatment

Edited by Aaron Lazare, MD

For the first time in any book on psychiatry, material on organic/functional differential diagnosis of syndromes is organized around the presenting psychiatric syndrome rather than the organic syndrome. This is particularly logical and helpful for the psychiatrist and one reason why no psychiatrist or mental health professional who must evaluate and treat the diverse population of ambulatory patients seeking help in outpatient settings should be without a copy of **Outpatient Psychiatry—Diagnosis and Treatment,** the only book with a comprehensive clinical focus on general outpatient psychiatry. Written by effective and experienced clinicians for other practicing clinicians, there is no more directly applicable and useful study available to improve the skills of the practicing clinical psychiatrist.

PRIMER OF LITHIUM THERAPY

By James W. Jefferson, MD and John H. Greist, MD

"This is a superior, concise but comprehensive, and very practical guide to the safe and effective use of lithium alone and in combination in the treatment of established clinical indications.... the authors have carefully and critically digested the voluminous world literature ... to provide physicians with very valuable, factual data on the art of rational lithium therapy ... This inexpensive *bible* on lithium is truly worth owning. It is highly recommended."—*International Drug Therapy Newsletter*

BIOFEEDBACK—Principles and Practice for Clinicians

Edited by John V. Basmajian, MD, FACA

"We offer this book as a timely summary and explication of the best applications of biofeedback treatment techniques to neurological, psychosomatic and psychological disturbances. The techniques are not final and complete, but the underlying principle is quite clear and substantiated. Provided with various electronic instrumental displays of covert responses, patients can acquire substantial voluntary control of them ... This book brings together in one volume the present state of the art."—*From the Preface*

PEDIATRIC PSYCHOPHARMACOLOGY
A Practical Guide to Clinical Application

By James H. White, MD

"In this volume the author has lucidly discussed the basic pharmacology of the psychoactive drugs as well as giving the practitioner an organized, practical guide to the use of the drugs in children. I feel that any physician or other professional who works with children should be thoroughly familiar with the wealth of useful data contained in this book. Dr. White has done an admirable job in organizing a tremendous amount of material and presenting it in a clear and practical form."—*From the Foreword by Dr. L. G. Hornsby, Professor of Psychiatry and Pediatrics, Univ. of Texas*

THE PRACTICING PHYSICIAN'S APPROACH TO HEADACHE
Second Edition

By Seymour Diamond, MD and Donald S. Dalessio, MD

Selected by *Behavioral Medicine* as one of the "10 outstanding psychiatric and psychological books of 1978," the journal said Diamond and Dalessio "have written probably the best available handbook on the subject of head pain. If there is a need for a comprehensive, practical publication on cluster, migrain, and muscle contraction headaches—and there is—this small volume has definitely answered the call ... Photos, diagrams, and case histories amply illustrate each chapter. Psycho-social factors in head pain are given the important discussion they deserve."

CLINICAL PSYCHIATRY IN PRIMARY CARE

By Steven L. Dubovsky, MD and Michael P. Weissberg, MD

Another choice by *Behavioral Medicine* as one of the "10 outstanding psychiatric and psychological books of 1978," this is an exciting new publication that outlines practical guides to the diagnosis and treatment of commonly encountered psychiatric disorders as seen by the primary care physician. Written especially for the non-psychiatrist, this crisis manual covers the physician's reaction to the patient, useful interventions in treatment, common successful and unsuccessful approaches to diagnosis and treatment, differential diagnosis, medications, and psychotherapy. Using it, the physician who would normally learn mainly through trial and error will be able to apply these guidelines for an effective and immediate response to psychiatric disorders or emergencies.

Brief Summary of Prescribing Information

ADAPIN® (doxepin HCl) Capsules

Indications—Relief of symptoms of anxiety and depression.

Contraindications—Glaucoma, tendency toward urinary retention, or hypersensitivity to doxepin.

Warnings—Adapin has not been evaluated for safety in pregnancy. No evidence of harm to the animal fetus has been shown in reproductive studies. There are no data concerning secretion in human milk, nor on effect in nursing infants.

Usage in children under 12 years of age is not recommended. MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug, as serious side-effects and death have been reported with the concomitant use of certain drugs and MAO inhibitors.

In patients who may use alcohol excessively potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions—Drowsiness may occur and patients should be cautioned against driving a motor vehicle or operating hazardous machinery. Since suicide is an inherent risk in depressed patients they should be closely supervised while receiving treatment. Although Adapin has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind.

Adverse Reactions—Dry mouth, blurred vision and constipation have been reported. Drowsiness has also been observed.

Adverse effects occurring infrequently include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as sweating, tachycardia and hypotension. Weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash and pruritus may also occur.

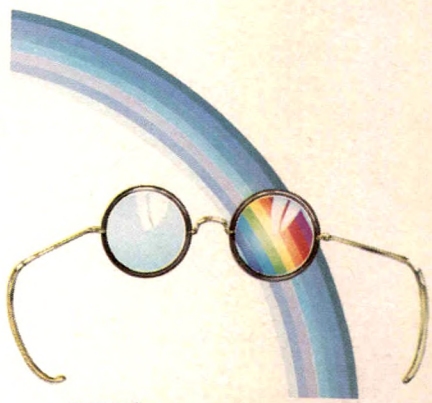
Dosage and Administration—In mild to moderate anxiety and/or depression: 25 mg t.i.d. Increase or decrease the dosage according to individual response. Daily dosage, up to 150 mg may be taken at bedtime without loss of effectiveness. Usual optimum daily dosage is 75 mg to 150 mg per day not to exceed 300 mg per day.

Antianxiety effect usually precedes the antidepressant effect by two or three weeks.

How Supplied—Each capsule contains doxepin, as the hydrochloride: **10 mg, 25 mg, 50 mg, and 100 mg** capsules in bottles of 100 and 1000.

For complete prescribing information please see package insert or PDR.

in anxiety/depression...



a good awakening from a good night's sleep

Most depressed patients experience some form of sleep disturbance. Adapin® helps relieve the accompanying anxiety, and restores a more normal sleep pattern right from the start of therapy.

☐ **convenient, flexible therapy**
The usual optimal dose is 75 to 150 mg daily. The entire dose may be given at night without loss of therapeutic effect. Adapin is available as 10 mg, 25 mg, 50 mg, and 100 mg capsules.

Adapin®

In moderate depression and anxiety

Only Limbitrol relieves this range of symptoms this rapidly.

And without a phenothiazine.

Limbitrol is indicated for the treatment of patients with moderate to severe depression associated with moderate to severe anxiety.

The therapeutic response to Limbitrol occurs earlier and with fewer treatment failures than when either amitriptyline or chlordiazepoxide is used alone.

Symptoms likely to respond in the first week of treatment include: insomnia, feelings of guilt or worthlessness, agitation, psychic and somatic anxiety, suicidal ideation and anorexia.

Limbitrol.
Dual therapy with greater specificity...without classical phenothiazine drawbacks.

ROCHE

recommendations for treatment are based
experience with its components. Primary
should be with the dangers associated with
one overdosage. Deaths by deliberate or acc-
verdosage have occurred with this class of

tients suspected of having an overdosage of
trol should be admitted to a hospital as soon as
sible.
anifestations. High doses may cause drowsiness,
mporary confusion, disturbed concentration or tran-
sient visual hallucinations. Overdosage may cause
hypothermia, tachycardia and other arrhythmias, ECG
evidence of impaired conduction (such as bundle
branch block), congestive heart failure, dilated pupils,
convulsions, severe hypotension, stupor and coma.
Other symptoms may be agitation, hyperpyrexia or any of those
muscle rigidity, vomiting, hypertonicity.
listed under Adverse Reactions.
Treatment: Empty the stomach as quickly as possible by
emesis or lavage. In the comatose patient a cuff
endotracheal tube should be placed in position prior to
either of these measures. The stomach also should be emptied of activated
charcoal into the stomach but responds to stimuli only
the patient is stuporous but responds to stimuli only
close observation and nursing care may be required. It is
essential to maintain an adequate airway and fluid in-
take. Body temperature should be watched closely and
appropriate measures taken should deviations
occur.
The intramuscular or slow intravenous administration of
1 to 3 mg in adults (or 0.5 mg in children) of physo-
stigmine salicylate (Antilirium®) has been reported to
reverse the manifestations of amitriptyline overdosage
Because of its relatively short half-life, additional doses
may be needed at intervals of 30 minutes to 2 hours.
Because the manifestations of amitriptyline overdosage
may be treated by the use of barbiturates, cardiac
anesthetic rather than the use of barbiturates. Cardiac
monitoring is advisable, and the cautious use of digitalis
or other antiarrhythmic agents should be considered if
serious cardiovascular abnormalities occur. Serum
potassium levels should be monitored and kept within
normal limits by the use of appropriate I.V. fluids. Stan-
dard measures including oxygen, I.V. fluids, plasma ex-
panders and corticosteroids may be used to control
circulatory shock.
Dialysis is unlikely to be of value, as it has not proven
useful in overdosages of either amitriptyline or chlor-
diazepoxide. Since many suicidal attempts involve mul-
tiple drugs including barbiturates, the possibility of
dialysis being beneficial for removal of other drugs
should not be overlooked.
Treatment should be continued for at least 48 hours,
along with cardiac monitoring in patients who do not
respond to therapy promptly. Since relapses are fre-
quent, patients should be hospitalized until their condi-
tions remain stable without physostigmine for at least 24
hours.
Since overdosage is often deliberate, patients may
attempt suicide by other means during the recovery
phase.

amitriptyline intoxication by physostigmine. JAMA
230:1433-1434, Dec 9, 1974

Dosage and Administration: Optimum dosage varies with the severity of the symptoms and the response of the individual patient. When a satisfactory response is obtained, dosage should be reduced to the smallest amount needed to maintain the remission. The larger portion of the total daily dose may be taken at bedtime. In some patients, a single dose at bedtime may be sufficient. In general, lower dosages are recommended for elderly patients.
Limbitrol 10-25 is recommended in an initial dosage of three or four tablets daily in divided doses; this may be increased to six tablets daily as required. Some patients respond to smaller doses and can be maintained on two tablets daily.
Limbitrol 5-12.5 in an initial dosage of three or four tablets daily in divided doses may be satisfactory in patients who do not tolerate higher doses.

How Supplied: White, film-coated tablets, each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) and blue, film-coated tablets, each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles of 100 and 500; Tel-E-Dose® packages of 100. Prescription Paks of 50.

LIMBITROL® TABLETS Tranquilizer—Antidepressant

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.

Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants: Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.

Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.)

***Usage in Pregnancy:* Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage; withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).

Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated: sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12.

In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.

Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.

This list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs:

Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.

Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.

Anticholinergic: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urinary tract.

Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.

Hematologic: Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.

Endocrine: Testicular swelling and gynecomastia in the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female and elevation and lowering of blood sugar levels.

Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaundice, alopecia, parotid swelling.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. I.V. administration of 1 to 3 mg physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestation and treatment.

Dosage: Individualize according to symptom severity and patient response. Reduce to smallest effective dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bedtime. Single *h.s.* dose may suffice for some patients. Lower dosages are recommended for the elderly.

Limbitrol 10-25, initial dosage of three to four tablets daily in divided doses, increased up to six tablets or decreased to two tablets daily as required. Limbitrol 5-12.5, initial dosage of three to four tablets daily in divided doses, for patients who do not tolerate higher doses.

Supplied: Limbitrol 10-25 tablets each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) and Limbitrol 5-12.5 tablets each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles of 100 and 500; Tel-E-Dose* packages of 100; Prescription Paks of 50.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

How to initiate and maintain therapy

Select dosage strength appropriate for each patient

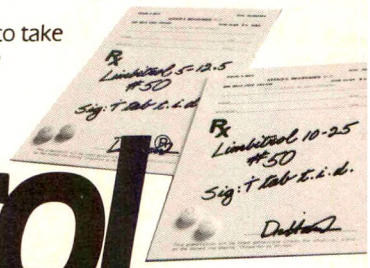
☐ Limbitrol 10-25 is recommended for most patients

☐ Limbitrol 5-12.5 may be indicated for those who do not tolerate higher doses and for elderly patients

Specify daily dosage based on symptom severity

☐ An initial dosage of three tablets is recommended.

☐ Dosage may be increased to six tablets or decreased to two tablets daily as necessary.



☐ Once a satisfactory response is obtained, evaluate response and, if necessary, reduce dosage to smallest amount needed.

Utilize dosage options to best accommodate individual patient needs

☐ T.I.D. or Q.I.D., familiar regimens most suited for patients who tolerate medication without undue drowsiness

☐ Two tablets one hour before bedtime and one tablet midday may minimize daytime drowsiness and help relieve a common target symptom—insomnia

☐ Entire dosage h.s. to take maximum advantage of the sedative effect

Limbitrol

Tablets 10-25 each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt)

Tablets 5-12.5 each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)

CIV

How to make each patient an informed patient

1. Discuss with patients the probability that they will experience drowsiness, especially during the first week.

2. Reassure your patients that drowsiness is one indication that the medication is working and that it may help alleviate their insomnia.

3. Encourage patients to report if drowsiness becomes troublesome so that, if necessary, dosage schedule can be adjusted or the symptom treated.

4. Caution patients about the combined effects with alcohol or other CNS depressants. Let them know that the additive effects may produce a harmful level of sedation and CNS depression.

5. Caution patients about activities requiring complete mental alertness, such as operating machinery or driving a car.

6. Warn pregnant patients and patients of childbearing age that the safety of Limbitrol in pregnancy has not yet been established.

Please see complete product disclosure for other pertinent information.

Limbitrol should not be used under the following circumstances:

1. Hypersensitivity to benzodiazepines or tricyclic antidepressants.
2. Should not be given with an MAO inhibitor. To replace an MAO inhibitor with Limbitrol, discontinue MAO inhibitor for a minimum of 14 days before cautiously initiating Limbitrol therapy.
3. During the acute recovery phase following myocardial infarction.

Announcing two volumes in the SEMINARS IN PSYCHIATRY MONOGRAPH *Series . . .*

Series Editor: MILTON GREENBLATT, M.D.

Psychopharmacology Update New and Neglected Areas

Edited by JOHN M. DAVIS, M.D. and DAVID GREENBLATT, M.D.

This volume deals with topics such as teratology, lithium effects on heart and kidney, pharmacology of the elderly, as well as recent progress in the areas of alcoholism, anxiety and personality disorders. The practitioner will find this presentation to be of inestimable value in the pursuit of quality care and treatment for psychiatric patients. The contributing authors include: B. Ameer; J. H. Greist; J. W. Jefferson; B. A. Jones; R. Kellner; L. W. Lazarus; S. F. Pariser; E. R. Pinta; R. T. Rada; E. A. Young.

1979, about 208 pp., $12.50 ISBN: 0-8089-1156-2

Methods of Biobehavioral Research

Edited by E. A. SERAFETINIDES, M.D., Ph.D.

This book is intended as a review and update of the range and variety of methods and techniques used in biobehavioral research today. It sets forth the basics of research methodology, makes the various research technologies better understood and the corresponding methods more familiar and accessible to the practitioners-and consumers-of these sciences. This is done by expert researchers covering such fields as neurobiochemistry, statistics, psychopharmacology, ethology, biofeedback conditioning and psychophysiology, EEG and neurophysiology, brain imaging techniques, computers, clinical, nursing and family therapy research including psychotherapy and socio-cultural aspects. The emphasis is on defining terms, explaining rationales, and describing the tools of some of the prevailing research approaches in the biobehavioral sciences.

1979, about 288 pp., about $21.50 ISBN: 0-8089-1173-2

Clinical Interpretation of Objective Psychological Tests

by CHARLES J. GOLDEN, Ph.D.

Presented here is the basic clinical knowledge and strategies necessary for the competent use of the most widespread and important tests in adult psychology today. The tests have been selected from the four major areas of psychological testing: intellectual evaluation, achievement, personality, and organic brain dysfunction. The tests are those most frequently used in each area as well as those which promise to be useful in a significant clinical area likely to be encountered by the average psychologist. The text is lucidly written so it can be understood by the individual with no specific background with a test or with psychological testing in general.

1979, 272 pp., illus., $17.00 ISBN: 0-8089-1163-5

Current Psychiatric Therapies Volume 18

Edited by JULES H. MASSERMAN, M.D.

This is the latest volume in a series which has achieved worldwide commendation and circulation for its clarity, objectivity and therapeutic helpfulness. Volume 18 presents the latest authoritative developments in the genetic, pharmacologic, environmental, esthetic, individual, familial, group and social modalities of various psychiatric therapies, in specific detail for clinical application.

1979, 336 pp., $34.50 ISBN: 0-8089-1151-1

WHEN L-TRYPTOPHAN THERAPY IS NEEDED . . . THE PROVEN BRAND NAME TO REMEMBER IS . . .

Tryptacin®
BRAND OF L-TRYPTOPHAN

and there are many good reasons why OLC Laboratories Tryptacin should be the brand of your choice:

- MANUFACTURED UNDER STRICTEST QUALITY CONTROL
- UNIFORM DOSAGE (Available in 125 mg, 250 mg, 500 mg scored tablets)
- LEADING SUPPLIERS FOR L-TRYPTOPHAN RESEARCH
- 20 YEARS EXPERIENCE IN SUPPLYING THE MEDICAL PROFESSION
- PREFERRED BY MOST HOSPITAL AND UNIVERSITY PROJECTS
- LISTED IN 1979 PHYSICIANS DESK REFERENCE (PDR)

AVAILABLE ON DIRECT BASIS OR THRU YOUR HOSPITAL OR COMMUNITY PHARMACY

FLORHENA
PROLIX

The Prolixin® (Fluphenazine) system of schizophrenia management—

spanning virtually every clinical situation

There is scarcely a patient-type presenting with schizophrenia that cannot be successfully managed with one of the numerous forms of Prolixin (Fluphenazine).

For the newly admitted, agitated patient, a first choice would be short-acting Prolixin Injection (Fluphenazine Hydrochloride Injection USP).

For long-term management of more "dependable" patients, you have the titration flexibility of four potencies of Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP).

For patients who "cheek" or otherwise resist tablet medication, you can utilize pleasant tasting, orange-flavored Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP).

For long-term maintenance of less compliant patients, you can employ unique, long-acting Prolixin Decanoate (Fluphenazine Decanoate Injection) and achieve effective neuroleptization for up to four weeks and longer with a single injection.

See next page for brief summaries.

PROLIXIN® (Fluphenazine Hydrochloride)
TABLETS/ELIXIR/INJECTION

Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP) provide 1, 2.5, 5, or 10 mg fluphenazine hydrochloride per tablet. Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP) provides 0.5 mg fluphenazine hydrochloride per ml (2.5 mg per 5 ml teaspoonful) with 14% alcohol by volume. Prolixin Injection (Fluphenazine Hydrochloride Injection USP) provides 2.5 mg fluphenazine hydrochloride per ml; it contains 0.1% methylparaben and 0.01% propylparaben as preservatives.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to fluphenazine hydrochloride and other antipsychotic drugs is not known.

Periodic checking of hepatic and renal functions and blood picture should be done. Monitor renal function of patients on long-term therapy; if BUN becomes abnormal, discontinue fluphenazine. "Silent pneumonias" are possible.

Abrupt Withdrawal: In general, phenothiazines do not produce psychic dependence. However, gastritis, nausea and vomiting, dizziness, and tremulousness have been reported following abrupt cessation of high dose therapy; reports suggest that these symptoms can be reduced if concomitant antiparkinsonian agents are continued for several weeks after the phenothiazine is withdrawn.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. Most often these symptoms are reversible, but they may be persistent. They include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, hyperreflexia. The incidence and severity of such reactions will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of an anti-parkinsonian drug such as benztropine mesylate and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may need to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines.

For full prescribing information, consult package inserts.

HOW SUPPLIED: *Tablets*—1 mg in bottles of 50 and 500; 2.5 mg and 5 mg in bottles of 50 and 500 and in Unimatic® single-dose cartons of 100; 10 mg in bottles of 50 and 500. *Elixir*—in bottles of 473 ml (1 pint) and in 60 ml dropper-assembly bottles with dropper calibrated at 0.5 ml (0.25 mg), 1 ml (0.5 mg), 1.5 ml (0.75 mg), and 2 ml (1 mg). *Injection*—in multiple-dose vials of 10 ml.

PROLIXIN DECANOATE®
Fluphenazine Decanoate Injection

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg fluphenazine decanoa per ml in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. patients who have a blood dyscrasia or liver damage, or who are receiving large doses hypnotics, or who are comatose or severely depressed. In patients who have shown hyperse sitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy m chinery may be impaired by use of this drug. Physicians should be alert to the possibility th severe adverse reactions may occur which require immediate medical attention. Potentiation effects of alcohol may occur. Safety and efficacy in children have not been established becau of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; wei possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused chole tatic jaundice, dermatoses or other allergic reactions because of the possibility of cros sensitivity. When psychotic patients on large doses of a phenothiazine drug are to under surgery, hypotensive phenomena should be watched for; less anesthetics or central nervo system depressants may be required. Because of added anticholinergic effects, fluphenazi may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosphor insecticides; in patients with a history of convulsive disorders since grand mal convulsions ha occurred; and in patients with special medical disorders such as mitral insufficiency or ot cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged thera there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal depos and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician exp enced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal functi and blood picture should be done. Renal function of patients on long-term therapy should monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneumoni are possible.

There is sufficient experimental evidence to conclude that chronic administration of antip chotic drugs which increase prolactin secretion has the potential to induce mammary neoplas in rodents under the appropriate conditions. There are recognized differences in the physiol ical role of prolactin between rodents and humans. Since there are, at present, no adequ epidemiological studies, the relevance to human mammary cancer risk from prolonged expos to fluphenazine decanoate and other antipsychotic drugs is not known.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most quently reported. Most often these symptoms are reversible, but they may be persistent. Th include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthoton hyperreflexia. Muscle rigidity sometimes accompanied by hyperthermia has been repor following use of fluphenazine decanoate. One can expect a higher incidence of such reacti with fluphenazine decanoate than with less potent piperazine derivatives or straight-ch phenothiazines. The incidence and severity will depend more on individual patient sensitivity, dosage level and patient age are also determinants. As these reactions may be alarming, patient should be forewarned and reassured. These reactions can usually be controlled administration of an antiparkinsonian drug such as benztropine mesylate and by subsequ reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometir irreversible tardive dyskinesia may appear in some patients on long-term therapy or may oc after discontinuation of drug. The risk seems greater in elderly patients, especially females, high dosages. The syndrome is characterized by rhythmical involuntary movements of tong face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chew movements) and may be accompanied by involuntary movements of extremities. Find out more about psychiatric advances from Britain

ORGANIC PSYCHIATRY: The Psychological Consequences of Cerebral Disorder. By William Alwyn Lishman, B.Sc., M.D., F.R.C.P., F.R.C.Psych., D.P.M. This important British publication focuses special attention on the psychological disturbances and psychiatric disorders that are the effects of cerebral disease. This book's unique approach (considers both neurology/psychiatry plus over 2,000 references) makes this the preeminent reference in neuropsychiatry. Put it to work for you — order your copy today! 1978. 1,000 pages. **Price, $65.00.**

THE MANY FACES

Help for the apathetic/ withdrawn geriatric*

For the aged person suffering from withdrawn or apathetic senile behavior, Ritalin can often help relieve bothersome symptoms. In one double-blind study[1] of withdrawn, apathetic geriatric patients, Ritalin elicited notable improvement in competence, interest and retardation. While no side effects were reported in this study, blood pressure and pulse variations were noted in both groups but were not considered of exceptional magnitude.

Help for narcoleptic patients

The narcoleptic patient can fall asleep anytime... anyplace... and the consequences can be grave, or at the least, embarrassing. Although there is no known cure for narcolepsy, Ritalin acts promptly to counteract sleepiness and is the medication most frequently used by cited investigators.[2,3] Occasional problems of tolerance may be managed by complete withdrawal of Ritalin during vacation or holidays, then reinstating the drug at lower dosage.[3]

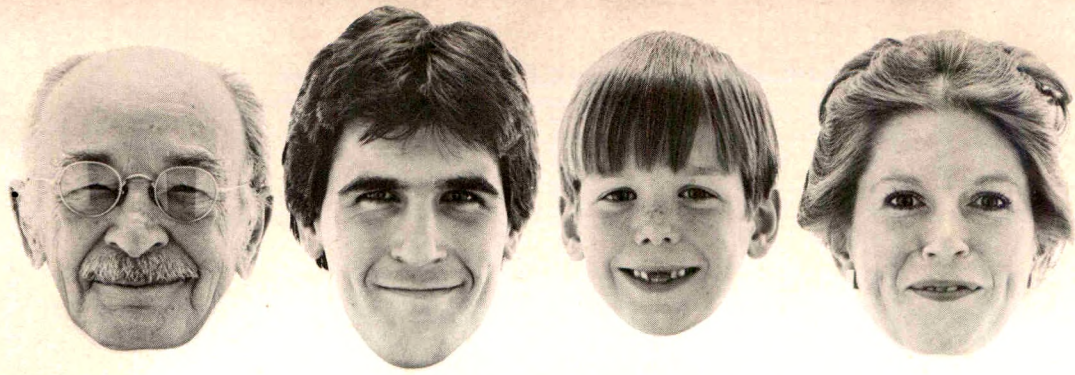
*Ritalin has been evaluated as possibly effective in these indications.

OF RITALIN® C II

(methylphenidate)

Help for patients with mild depression*

As Ritalin acts promptly to relieve symptoms of mild depression, mood and outlook usually improve, and the patient can cope again. Generally, one prescription is sufficient. Ritalin is contraindicated in severe depression.



Help for the MBD child

For the child with Minimal Brain Dysfunction (MBD), adjunctive Ritalin is often highly effective when medication is needed to help reduce symptoms such as distractibility,[4] disorganized behavior,[4] and hyperactivity.[4] MBD children responding to Ritalin usually exhibit better classroom performance and improved interpersonal relationships. Moreover, as MBD symptoms are curbed, the affected child often responds more positively to nonpharmacologic modalities.[5] Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is temporarily or permanently discontinued.

(methylphenidate hydrochloride USP)

TABLETS

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
Effective: Minimal Brain Dysfunction in Children—as adjunctive therapy to other remedial measures (psychological, educational, social)
Special Diagnostic Considerations
Specific etiology of Minimal Brain Dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.
Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate to severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.
Drug treatment is not indicated for all children with MBD. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.
Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.
Effective: Narcolepsy
"Possibly" effective: Mild Depression; Apathetic or Withdrawn Senile Behavior
Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS
Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.
Sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.
Ritalin should not be used for severe depression of either exogenous or endogenous origin.
Ritalin should not be used for the prevention or treatment of normal fatigue states.
There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.
Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.
Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions
Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.
Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy
Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence
Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.
Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS
Patients with an element of agitation may react adversely; discontinue therapy if necessary.
Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS
Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been report
Although a definite causal relationship has not be
established, the following have been reported in
tients taking this drug: leukopenia and/or anemia
few instances of scalp hair loss.
In children, loss of appetite, abdominal pain, wei
loss during prolonged therapy, insomnia, and
tachycardia may occur more frequently; howeve
any of the other adverse reactions listed above r
also occur.

DOSAGE AND ADMINISTRATION
Adults
Administer orally in divided doses 2 or 3 times da
preferably 30 to 45 minutes before meals. Dosag
will depend upon indication and individual response.
Average dosage is 20 to 30 mg daily. Some patie
may require 40 to 60 mg daily. In others, 10 to 15
daily will be adequate. Patients who are unable t
sleep if medication is taken late in the day should
take the last dose before 6 p.m.

Children with Minimal Brain Dysfunction
(6 years and over)
Start with small doses (*eg*, 5 mg before breakfas
and lunch) with gradual increments of 5 to 10 mg
weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after
appropriate dosage adjustment over a one-mon
period, the drug should be discontinued.
If paradoxical aggravation of symptoms or other
verse effects occur, reduce dosage, or, if neces
discontinue the drug.
Ritalin should be periodically discontinued to as
the child's condition. Improvement may be sustained when the drug is either temporarily or per
nently discontinued.
Drug treatment should not and need not be inde
and usually may be discontinued after puberty.

HOW SUPPLIED
Tablets, 20 mg (peach, scored): bottles of 100 a
1000.
Tablets, 10 mg (pale green, scored): bottles of 1
500, 1000 and Accu-Pak® blister units of 100.
Tablets, 5 mg (pale yellow): bottles of 100, 500 a
1000.

Six Lives/Six Deaths

Portraits from Modern Japan

Robert Jay Lifton, Shūichi Katō, and Michael R. Reich

Focusing on how six talented Japanese writers and public figures prepared for their deaths, this book is a major study of cultural change in Japan. Each biographical sketch places the man studied in his historical and cultural milieu, contains pertinent psychological observations, and includes a key document written as he approached death. $16.95

Legend, Myth, and Magic in the Image of the Artist

A Historical Experiment

Ernst Kris and Otto Kurz
Preface by Sir Ernst Gombrich

In this pioneering work, Ernst Kris and Otto Kurz show how the stories told about the lives of artists, in all ages and cultures, reflect a profound human response to the mystery and magic of image making. The book is a combination of enormous learning in the history of art and brilliant psychoanalytic insight. $15.00

Freud and the Problem of God

Hans Küng
translated by Edward Quinn

Here one of the world's most exciting theologians focuses his attention on the question of Freud's atheism. In the course of his discussion, Küng traces Freud's views on religion and religious longing, presents for comparison the attitudes toward religion of Jung and Adler, and shows finally that Freud's arguments against the existence of God are theologically unsound. He concludes with a frank and provocative discussion of what psychoanalysis may be able to teach the Catholic Church. $8.95

The Brown Schools: Specialists in Residential Treatment

Residential treatment has become highly specialized in the field of mental health. It is a specific treatment modality for those who need a totally planned and structured environment.

The Brown Schools has developed a wide range of professional services that can be utilized to implement an individually planned residential treatment program. The degree of structure and protection, the intensity of therapy, the methods of education and training are controlled and modified with the resident's changing needs.

Professionals in the areas of psychiatry, psychology, nursing, social work, education, prevocational training, speech pathology, and recreation have developed expertise in the specific area of residential treatment. Each service area is designed as a component of an integrated therapeutic milieu.

The three residential treatment centers of The Brown Schools provide complete programming for those in need of twenty-four hour care. Services are available for children, adolescents, and adults with emotional disturbance, mental retardation, and neurological impairment. Two small group homes in Austin provide for reintegration into the community and complement the services offered in the other centers. For information, write:

An equal opportunity employer. All our programs are accredited by the appropriate Councils of the Joint Commission on Accreditation of Hospitals.

The patient with clinically significant depression

He's getting better... and ELAVIL®

(AMITRIPTYLINE HCl | MSD)

is helping

Helping with symptom relief

ELAVIL usually relieves a broad range of symptoms associated with depression, including sleep disturbance, one of the most frequently observed in the "constellation of symptoms," and usually the first symptom to respond to therapy.

And, the anxiety-reducing sedative component extends the drug's clinical value when depression is accompanied by symptoms of anxiety. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol.

Helping with convenient dosage regimens

ELAVIL offers a variety of convenient dosage regimens. A once-daily bedtime regimen may be an effective prescribing option, particularly when taken by a depressed patient experiencing sleep disturbance. ELAVIL can also be prescribed in divided daily doses. Prescriptions should be written for the smallest amount feasible.

Providing a wide range of tablet strengths

ELAVIL offers six color-coded tablets, available in the following strengths: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg. And for special circumstances, an injectable form is available. Injection ELAVIL is supplied in 10-ml vials, 10 mg/ml.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg
INJECTION: 10 mg per ml

Elavil®
(AMITRIPTYLINE HCl | MSD)

helping relieve the symptoms of clinically significant depression

MSD
MERCK SHARP & DOHME

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

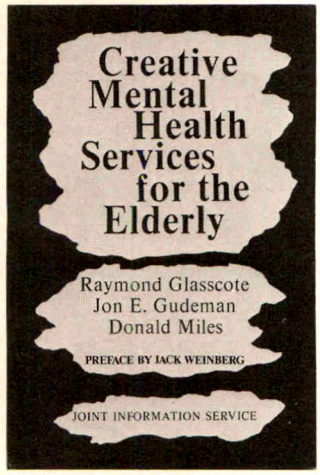
Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.

When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.



How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

J8EL26 (116)

The Joint Information Service of the American Psychiatric Association and the Mental Health Association releases Two New Volumes That

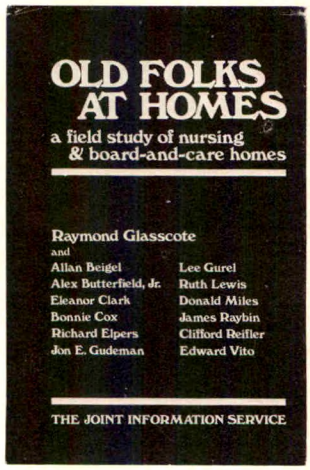
Focus on the Elderly

This carefully documented book reports a field study of ten programs, four in America and six in England and Scandinavia, which serve as practical demonstrations of creative mental health services for the elderly. They include:

- a novel "Neighborhood Family" providing vigorous support to elderly residents of several trailer parks
- a high school for the elderly which sends its students abroad for study trips
- a "Human Development Project" that focuses on responding to the psychological needs of the elderly
- a carefully coordinated system of "respite hospitalization," which promotes the health of the elderly while allowing maximum use of hospital beds and family resources
- a "Lucy Booth," patterned after the Peanuts comic strip, which provides easy access to many kinds of services
- and many other innovative, successful approaches.

Each program is subjected to intensive scrutiny. The resulting document becomes a handbook, and, as well, a forum through which some of the world's most experienced practitioners of "the psychiatry of old age" present their views.

Dr. Wilma Donohue, director of the International Center for Social Gerontology, characterizes this volume as "a masterful job of putting everything in relief . . . the guidelines for action are right here."



190 pages. Casebound. Price $8.50.

Concerned about the very bad reputation that nursing homes have received from many quarters in recent years, the Joint Information Service set up a field study to visit a systematically chosen sample of nursing homes, and board-and-care homes as well, to see to what extent the care of and the quality of life for the patients differed from the geriatrics units of state hospitals. Altogether, sixty nursing homes and 31 board-and-care homes in ten locales were visited, in each case by the senior author accompanied by two mental health professionals.

The teams were surpised to learn that care and quality of life in many of the nursing and board-and-care homes they visited were better—sometimes dramatically better—than that in the mental health facilities and often at lower cost.

This unique publication provides an overview of all facilities visited plus vignettes of approximately half. Federal and state rules and regulations are also expertly synthesized into brief and readable style.

148 pages. Casebound. Price $6.50

a consideration beyond efficacy alone...

Infrequent akathisia and other disabling extrapyramidal effects...

The rapidly rising readmission rate among discharged psychotic patients is mainly due to noncompliance with antipsychotic drug therapy. And this, in turn, may be largely attributed to disabling extrapyramidal side effects, notably akathisia.[1]

Although extrapyramidal effects are characteristic of antipsychotic agents in general, with Mellaril (thioridazine) such effects are infrequent. Adding an antiparkinsonian agent—which can cause its own side effects—can usually be avoided. Mellaril (thioridazine) is contraindicated in patients with severe hypotensive or hypertensive heart disease.

Extrapyramidal Effects of Selected Antipsychotic Agents*[2]

DRUG	EXTRAPYRAMIDAL EFFECTS
Chlorpromazine	Moderate
Perphenazine	High
Prochlorperazine	High
Fluphenazine	High
Acetophenazine	Moderate
Trifluoperazine	High
Chlorprothixene	Moderate
Thiothixene	Moderate
Haloperidol	High
MELLARIL® (thioridazine)	Low

Based on antipsychotic dosage ranges

Mellaril® (thioridazine)

ABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP

ELLARIL-S™ (thioridazine) SUSPENSION, per 5 ml: thioridazine ase equivalent to 100 mg thioridazine HCl, USP

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

THE AMERICAN JOURNAL OF PSYCHIATRY

Research on the Psychosocial Treatment of Schizophrenia: A Summary Report

BY LOREN R. MOSHER, M.D., AND SAMUEL J. KEITH, M.D.

The authors present an overview of research on psychosocial treatments for schizophrenia. Findings from studies of five therapeutic approaches—individual psychotherapy, group psychotherapy, family therapy, milieu therapy, and community support systems—are discussed in detail. The usefulness of each type of therapy is critically assessed on the basis of available data from controlled outcome studies. The authors make recommendations regarding high-priority areas to be addressed in future studies of psychosocial treatment.

ALTHOUGH WE have learned a great deal about the design of research on psychosocial treatment, the data now available are sufficiently flawed to lead us to eschew categorical "yes, it works" or "no, it does not work" statements about a given therapeutic approach. The most common failings of the currently available studies are as follows:

1. Insufficient exposure to the particular intervention. The treatment is not given a reasonable chance to demonstrate its ability to produce change. By their very nature, psychosocial treatments cannot be expected to produce rapid, dramatic changes. For example, Hogarty and associates (1) did not see significant beneficial effects from major role therapy until patients had completed 18 months of treatment, and these effects were even more pronounced at 24 months.

2. Failure to define adequately the characteristics of the psychosocial intervention, the therapists, and the patients. Some studies report results from undefined individual therapy delivered by inexperienced therapists, fail to assess the fit between patient and therapist, and make no attempt to study whether therapy was in fact taking place. The mere juxtaposition of patients and therapists in a room for an hour does not ensure that therapy is being given.

3. Use of inappropriate outcome measures. Unfortunately, rehospitalization has retained its preeminent position as the most widely cited outcome variable, despite the fact that myriad non-patient-related factors are known to affect rehospitalization (e.g., administrative policies, availability of nonhospital resources for care, type of living arrangements, family emotional climate). In addition, psychosocial treatments address their major efforts to enhancing social adjustment, which has only a modest relationship to recidivism. Despite this, many psychosocial treatment studies have not assessed systematically the variables that are particularly relevant to this type of treatment, e.g., ability to work and social and interpersonal skills.

Evaluation of research on patients labeled "schizophrenic" is almost always plagued by questions about the type of patients included in this heterogeneous category. Although differences in results might be accounted for by subtle differences in patient characteristics, in most cases only the categories "acute" or "first admission" as contrasted with "chronic" or "long-term" have much influence on results. Insofar as is possible, we will include in this review a description of research samples as acute or chronic and inpatient or outpatient.

Received July 11, 1978; accepted Nov. 7, 1978. An earlier version of this paper was prepared by the authors for inclusion in Parloff M, Wolfe B, Hadley S, et al (eds): Assessment of Psychosocial Treatment of Mental Disorders: Current Status and Prospects; report submitted to the Institute of Medicine, National Academy of Sciences, February 1978.

INDIVIDUAL PSYCHOTHERAPY

The use of individual therapy with schizophrenic patients grew out of the psychoanalytic movement. Although psychoanalysis had European origins, the work of Meyer (2) and Sullivan (3) in this country provided a fertile ground for its transfer and use with schizophrenic patients here. Interest in individual psychoanalytic therapy with schizophrenics grew dramatically in the 1950s and early 1960s. This burgeoning interest was in part responsible for research conducted to assess the efficacy of such therapy during those years. It should be noted that most of the patients who received this treatment did so in a very small number of private treatment facilities (e.g., Chestnut Lodge and the Menninger Clinic). However, because of the influence of psychoanalysis in university departments of psychiatry and the prolific writings of some analysts (e.g., Arieti and Searles), the impact of the treatment of these relatively few patients was far greater than their numbers.

Controlled Research

Current doubts about the usefulness of individual psychotherapy as a treatment for schizophrenic patients stem from the negative results of controlled outcome studies in the 1960s, the development of clearly effective drug treatment, and the waning influence of psychoanalysis in departments of psychiatry. In the 1960s, there were four major studies in which schizophrenic inpatients treated with psychotherapy were compared to those who received other forms of treatment. The sample selection and individual psychotherapy techniques are summarized below:

1. Grinspoon and associates (4) studied single, male, chronic schizophrenics who had been hospitalized for more than 3 years in a large state hospital and treated with an analytically oriented approach by experienced therapists.
2. May (5) reported on first-admission "middle prognosis" schizophrenics treated with an ego-supportive approach, primarily by state hospital residents.
3. Karon and Vandenbos (6) studied acute, lower class, inner-city first-admission schizophrenics who were given either direct analysis or ego analysis by both experienced and inexperienced psychologists.
4. Rogers and associates (7) studied a mixed group of acute and chronic state hospital schizophrenics treated with client-centered therapy, primarily by experienced psychologists.

Several extensive critical reviews of these studies are available (8–10).

The fall from favor of individual psychotherapy as a treatment for schizophrenia is dramatically illustrated by the following: when one of the four studies was being designed in 1960, it was regarded as unethical for a control group not to receive psychotherapy, but by 1968 it was considered unethical to give a control group in another study psychotherapy alone.

Of the four controlled psychotherapy studies conducted during this period, those by Grinspoon and associates (4) and May (5), both of which had largely negative results, became the most widely known and influential. The two other studies (6, 7) had more positive results. Each of the four studies, viewed in retrospect, had critical design problems that led many scientists to warn against the premature conclusion that individual psychotherapy is of no value with schizophrenics. For example, Grinspoon and associates (4) focused on a small group of very chronic "back ward" patients who were transferred from a large state hospital into a highly staffed, nurturing, but undemanding milieu. We now know that for the chronic patient the dependency-reinforcing effects of such a milieu are likely to outweigh any possible benefit derived from 4 or 5 hours of individual therapy, even when it is provided by highly experienced therapists such as those in the Grinspoon and associates study.

The influential study by May (5) had two major flaws as a test of individual therapy: inexperienced state hospital residents served as therapists, and the subjects (middle-prognosis first-admission schizophrenic patients) received relatively few hours of therapy (an average of 46). It should be remembered that despite the prevailing negative zeitgeist about individual psychotherapy for inpatient schizophrenics, Karon and Vandenbos (6) reported positive results from their controlled study and Rogers and associates (7) obtained equivocally positive results. However, the more positive studies also had enough design problems to make it unwise to draw firm conclusions at this time about the value of individual psychotherapy for inpatient schizophrenics.

Fortunately, there is now a collaborative study under way at McLean Hospital and Boston University, under the direction of Alfred Stanton and Peter Knapp, that addresses may of the problems of previous research on inpatients treated by intensive psychotherapy. The patients are relatively acute, the therapists are experienced, the treatment will continue over a prolonged period and into the outpatient phase (a year or more), the outcome measures are appropriate to this treatment, whether therapy is in fact going on will be assessed, and the therapists and their fit with the patients will be studied.

Since the publication of the four inpatient studies in the 1960s, four posthospitalization comparisons of group and individual therapy with heterogeneous populations of schizophrenic patients have been published (11–14). In terms of readmission, three showed individual therapy and group therapy to be similar and one (14) found an advantage for group therapy. The two studies that measured social adjustment found opposite results, one in favor of group therapy (13) and the other in favor of individual therapy (12).

In general, these studies also suffer from design problems, especially with regard to control of neuroleptic drugs, assessments of whether therapy was actually taking place, and use of appropriate outcome

measures. However, the data seem to indicate that group therapy has some advantages, in terms of patient and therapist satisfaction, over individual therapy for the more chronic patients. There are no data on strictly acute patients treated with individual therapy after discharge. Nor are there data on whether group and individual therapy might be synergistic for some patients. Both of these deficiencies should be remedied by a new generation of studies.

GROUP PSYCHOTHERAPY

As far as its history is determinable, group psychotherapy appears to have grown out of the observation that patients with similar medical or psychological problems can receive benefit from each other as well as from the doctor. From its origins in lectures for mental reeducation of hospitalized patients (15, 16), group treatment of schizophrenia has diversified into many forms, including supportive therapy, psychodynamic therapy, and activity groups. Neither the early didactic techniques designed to instill understanding of the psychological mechanisms underlying behavior through classroom presentations and lectures (17–19) nor the strictly psychoanalytic approaches introduced during the same period (20–23) remain in wide use with schizophrenic patients today.

Although the primary aim in most traditional group therapies is facilitation of insight into personal and interpersonal problems, much group work with schizophrenics is oriented toward providing support, an environment in which patients can develop social skills, or a format that allows friendships to begin and be sustained.

There are many reviews of the group therapy outcome literature extending up to 1968 (24–27). Considering the data available to them, these reviewers generally concluded that most controlled evaluations of group therapy with schizophrenics (especially long-term inpatients) showed meager, if any, therapeutic benefit. There were individual instances of special benefits from group treatment, but design problems, such as lack of follow-up, inappropriate control groups, and insufficient duration of treatment, made it difficult to draw firm conclusions. This review will focus on the 1966–1976 decade of research.

Comparison with the Usual Hospital Treatment Program

Hospital settings almost always provide a wide range of treatment modalities, e.g., recreational and occupational therapy, music therapy, and medication. Therefore, group psychotherapy offered in inpatient settings is an "add-on" rather than an exclusive treatment form. In each of six studies of group therapy versus no group therapy reviewed by Parloff and Dies (28), patients selected for their predicted suitability for group therapy were randomly assigned to either group therapy or a no-group-therapy hospital treatment control group. Unfortunately, as is so often the case, diverse measures of outcome were used, with little overlap between studies, making direct comparisons difficult.

Of six comparisons of group therapy of schizophrenics against a no-group-therapy hospital condition, four failed to reveal any unique or impressive contribution assignable to group psychotherapy (28). It should be noted, however, that the studies with positive results (29, 30) were better designed in terms of length of treatment and outcome measures that addressed the investigators' hypotheses directly.

Group Therapy Combined with Other Psychosocial Interventions

Five of the six studies that tested group therapy in combination with another treatment approach reported that the combination—be it neuroleptic drugs, videotape feedback, ward activity, or dyadic social interaction—was superior to the treatment forms offered singly (28).

Integrating the results of these two types of in-hospital studies is difficult for a number of reasons: the patient groups are often not comparable, the outcome measures vary widely and frequently do not address the specific effects sought by the treatment, and many of the studies involve short treatment periods. This problem is especially relevant when the subjects are long-stay patients (as was the case in all but two of the studies). However, positive results were found by those investigators who carefully defined the behaviors or attitudes they wished to change and used outcome measures that tapped them. In addition, it appears that the more structured the activity—Olson and Greenberg's incentive therapy (29), Corder and associates' required dyadic interaction (31), and Robinson's videotape feedback (32)—the more likely a positive result (33). Although this interpretation is somewhat speculative, it is consistent with the types of milieu therapy found to be most useful for chronic patients.

Aftercare Treatment Studies

The treatment of schizophrenics has been revolutionized during the past 15 years. Extended hospitalization has given way to early release, and treatment is increasingly provided in general hospitals and outpatient settings rather than in large mental hospitals. Patients are discharged into the community, to their families, to halfway houses, or to foster homes with greater frequency. As this emphasis on community treatment has grown, it has become apparent that psychosocial interventions are required to aid the patient in maintaining community adjustment—drugs do not teach social and interpersonal skills. Group psychotherapy has been used as a treatment modality aimed at maintaining the discharged patient in the community by enhancing social and interpersonal skills.

During the past decade six major studies (11–14, 33, 34) have tested the relative efficacy of some form of group therapy contrasted with an alternative treatment

or a no-therapy control group in posthospitalization patients.

These recent studies of group psychotherapy given to heterogeneous groups of posthospital schizophrenics have not yielded strong or consistent evidence that this form of treatment reduced rates of rehospitalization, improved vocational adjustment, diminished psychopathology, or enhanced social effectiveness when compared with individual therapy or no-group-therapy control groups. However, because the evidence on each of these variables is contradictory and the therapy was not well defined, it cannot be concluded that outpatient group therapy is not useful for schizophrenics. In fact, a treatment whose principal aim is to promote socialization and enhance interpersonal skills probably should not be expected to have a striking effect on rehospitalization or vocational adjustment. Two of the three studies that addressed the socialization and interpersonal skills outcome variables (13, 34) showed a positive effect from group treatment. The negative findings of Levene and associates (12) were based on relatives' ratings, whereas the positive findings of the other two studies (13, 34) came from research raters and the patients themselves. This raises a methodologic issue that was also present in the inpatient group therapy studies, i.e., the influence of the rater on the assessment of outcome. It is also noteworthy that O'Brien and associates (13) and Herz and associates (11) reported that both group patients and group therapists retrospectively reported more favorable feelings about the treatment experience than did individually treated patients and their therapists. These morale-enhancing, affiliative effects are probably very important and certainly need further research, because they are particularly difficult issues with long-term, community-based patients.

What is badly needed now are comparative studies in which group or individual therapy is used to treat relatively acute patients; treatment should be started after the patients' psychoses have subsided but while they are still in residential care, and it should be continued into their posthospital period. The design should include patients maintained on and patients withdrawn from neuroleptic drugs. In addition, the therapy should be for a prolonged period (at least 6 months), the outcome measures should be focused primarily on social and interpersonal variables rather than rehospitalization rates, and a 2-year follow-up assessment period should be required. Finally, the samples should be sufficiently large to allow subgroup analysis in order to distinguish the types of patients who respond especially well, or poorly, to each form of treatment. The last condition will probably necessitate large-scale collaborative research.

FAMILY THERAPY

Although family therapy has been in widespread use for more than 15 years, there have been only three controlled comparative studies of its effectiveness with schizophrenics (35–38). All of these studies were conducted with relatively acute patients and the therapy was short-term (6–10 sessions). Ro-Trock and associates (38) compared 10 sessions of inpatient family therapy (focused on promoting clear communication and shifting the balance of maladaptive relationships within the family so that new, more adaptive forms of relating would be possible) and individual therapy (focused on helping the patient develop solutions and problem solving skills in dealing with life conflicts). Langsley and associates (37) compared hospitalization and "usual" treatment with family therapy aimed at quickly reducing the level of tension so that family resources could be garnered to cope more effectively in the crisis situation. Goldstein and associates (35, 36) compared 6 sessions of family therapy begun immediately after discharge with usual immediate post-discharge treatment, including maintenance neuroleptic drugs. The family therapy had four major goals: 1) promoting acceptance of the occurrence of the psychosis, 2) identifying precipitating stresses, 3) looking at possible future similar stressful events, and 4) developing strategies for avoiding, minimizing, and coping with these stresses.

Each study found family therapy to have advantages over the treatment with which it was being compared. Langsley and associates (37) concluded that family crisis intervention could be effective in preventing hospitalization for schizophrenics, but at 18-month follow-up, the patients' crisis management skills had not been significantly enhanced by the treatment.

Ro-Trock and associates (38) found that family therapy was associated with fewer readmissions and more rapid return to functioning in the community than individual therapy. They could not, however, identify any clear and consistent differences between the two treatments on their interaction and self-report measures. Goldstein and associates (36) found significant differences favoring family therapy at the end of the treatment in terms of reduced symptomatology and enhanced psychosocial adjustment. However, at 6-month follow-up only the "good premorbid" subsample of the family therapy subjects was functioning significantly better than the control subjects.

In addition to these controlled studies, there are a number of uncontrolled studies of longer term family therapy that included a substantial percentage of chronic patients (39-42). In each instance the investigators concluded that family therapy had resulted in greater improvement than would have been expected in its absence.

Given the lack of clearly negative results from family therapy, it is difficult to understand why so few studies of this type of treatment are available. Because family therapy is in widespread use in both inpatient and outpatient settings, research on its efficacy should be stimulated and supported. In particular, this research should compare longer-term family therapy (6–12 months) with another psychosocial treatment; the

sophisticated approach of Goldstein and associates (36) to the neuroleptic drug variable and subgroup analysis should be combined with the family interaction methodology of Ro-Trock and associates (38). In addition, the design should include 1- to 2-year posttreatment assessment of community adjustment and family interaction. Because of the origins and theoretical underpinnings of the family approach, this research might best be focused primarily on late adolescent and early adult schizophrenics living with their families of origin.

MILIEU TREATMENT

Over the past decade, marked progress has been made in defining, clarifying, and doing research on what constitutes a therapeutic milieu (43). Specific milieu typologies have been developed from new instruments designed to assess milieu characteristics systematically (44). The differing characteristics of inpatient milieus most useful for acute as compared with chronic patients have been described clinically. Acute patients have been found to recover best in highly staffed, accepting, supportive, stimulus-decreasing (at least early in treatment), relatively long-stay (3–5 month) environments in which psychosocial interventions are viewed positively (45–47).

In addition, four milieu characteristics associated with better posthospitalization psychosocial adjustment among relatively acute patients have been identified through the use of recently developed systematic assessment instruments (44, 48): 1) small size, 2) positive staff expectations, 3) line staff's active involvement and investment in the treatment process and decision-making (resulting in high morale), and 4) a practical, down-to-earth, problem-solving orientation (49–52). Intriguingly, these important milieu characteristics have been demonstrated only recently, after a long history of research that found little relationship between in-hospital milieu characteristics and posthospitalization adjustment among acute patients. Although derived completely independently, these characteristics are quite consistent with the clinical analysis of "good" milieus for acute patients described above.

Three recent clinical studies are noteworthy in having demonstrated that outcome (in terms of rehospitalization and posthospitalization social adjustment) was as good (45) or better (47, 53) in unmedicated patients as in patients treated with neuroleptic drugs. These findings are contrary to previous reports (8) in which milieu without neuroleptic drug treatment was reported to be relatively ineffective with acute patients. In effecting change without using neuroleptics, these newer studies would seem to have provided a specifically therapeutic milieu. This research is also important because of the emerging evidence of severe long-term toxicities of neuroleptics (e.g., tardive dyskinesia, breast cancer). That is, it is now possible to design milieu programs in which neuroleptic drug use can be minimized. However, a great deal of research is necessary before the fits between patient and milieu characteristics and need for drug treatment can be defined precisely. Given the emerging picture of neuroleptic toxicities, these studies warrant immediate stimulation and support.

In contrast to the clinical descriptions of good milieus for acute patients, chronic patients seem to respond best to a very structured, highly organized, high-expectation milieu oriented toward specific behavior change (54). In addition, chronic patients do best when the changes sought and the procedures for bringing them about are very clearly and specifically defined. There is also evidence that neuroleptic drug treatment interferes with the ability of some very chronic patients to learn new, more adaptive, socially appropriate behaviors in task-focused milieu programs (55).

For chronic patients, posthospital adjustment seems to be related to the degree to which behaviorally focused inpatient milieus have taught them adaptive behaviors and skills and have suppressed symptomatic and maladaptive behaviors. In addition, however, it appears important that the in-hospital program be continued for some time in the community and that a variety of supportive arrangements be available indefinitely (55, 56). Given a behavior-therapy-oriented program with continued aftercare and an adequate community residential program, more than 90% of very chronic patients can be discharged into the community, with a 2-year rehospitalization rate of less than 5% (54). Although only 10% of these patients will be able to live completely independently, they are able to function well enough to fulfill their basic needs for food, shelter, socialization, and recreation.

The recent findings in milieu research are striking in their consistency, replicability, and clinical relevance. Moreover, they can be implemented, with appropriate modifications, in settings where acute, chronic, or both types of patients are treated.

REHABILITATION

Psychosocial rehabilitation services, which began when a group of former state mental hospital patients banded together in New York in the late 1940s, have come to represent a major force in responding to the needs of the chronic schizophrenic population. The active collaboration of patients in the programs has been maintained, and the services have developed with professional leadership. The general goal is reintegration of the psychiatrically disabled into the community by maintaining and augmenting whatever level of functional independence a patient has been able to achieve. In general, rehabilitation has focused on programs to develop social support and independent living capabilities, emphasizing vocational components.

Results of research on the chronic patient popu-

lation have underlined the need for rehabilitation programs for this high-recidivism and low-employment group. An extensive review of research findings by Anthony and associates (57) showed baseline readmission figures of 30%–40% after 6 months, 35%–50% after 1 year, and 60%–75% after 3–5 years. In terms of employment, most studies indicate a 10%–30% rate of independent employment at follow-up, regardless of the time period studied. Unfortunately, little controlled comparative research has been carried out on the impact of comprehensive psychosocial rehabilitation centers on recidivism and employment.

Beard and associates (58) have recently reported on a 5-year follow-up study which showed that with an active outreach program for the initial 2 years of participation, Fountain House clients had significantly lower rehospitalization rates at 1, 2, and 5 years than control subjects. Those who were rehospitalized spent 40% fewer days in the hospital than rehospitalized control subjects. Their data also indicate that the more contact patients had with the program, the less likely they were to be rehospitalized.

Other aspects of comprehensive rehabilitation programs that have received research attention are aftercare clinics and transitional living arrangements. Aftercare clinics, which usually include some form of therapeutic or casework contact in addition to medication, have been shown to reduce readmission rates (59). Evidence indicates that this effect results from a combination of factors—drugs, additional services, and the type of patients who attend. Hogarty and associates (60) reported that patients who received major role therapy (casework with an experienced social worker) plus drugs had significantly better social adjustment than those who received drugs alone. This effect first appeared at 18 months and was somewhat stronger at 24 months. An interesting patient variable, chronicity (a composite rating based on the number of previous hospitalizations, length of last hospitalization, psychotic versus nonpsychotic diagnoses, and previous employment status), has also been shown to predict outcome (61). Kirk (61) reported that the recidivism rate of aftercare clinic attenders who had a high level of chronicity decreased as the number of visits increased to above six. In contrast, the recidivism rate of aftercare clinic attenders who had a low level of chronicity was not affected by an increased number of visits. Based on the results of this and another recent study (62), as well as the Fountain House results, it is tempting to conclude that aftercare treatment is most effective with those chronic patients who maintain a continuing relationship with the program.

Transitional facilities (halfway houses, day centers) are a major component of psychosocial rehabilitation and have been shown to be effective in reducing recidivism as long as the patients remain in contact with the facility (59). In their review, Rog and Raush (63) found data to suggest lower recidivism rates for residents of halfway houses, although they noted the almost complete absence of controlled studies. Successful programs have also been developed using a transitional person rather than a transitional facility to reduce readmission (64–66).

The field of psychosocial rehabilitation is experiencing a rapid expansion of its activities, as indicated by the establishment of the International Association of Psychosocial Rehabilitative Services and NIMH's new Community Support Program (a major component of which is psychosocial rehabilitative services). High priority should be given in this field to studies obtaining basic recidivism and employment data from several centers in an attempt to replicate the Fountain House results. Following this initial research effort more complex studies of patients' skill gains, quality of life, and satisfaction with services, as well as patient/program "fit" and patient/society benefits, should be implemented.

COMMUNITY SUPPORT SYSTEMS

The past decade has seen a gradual emergence of interest in a variety of community-based resources that, taken together, provide important support to schizophrenic patients. At least 10 different potential elements of community support programs have been identified (67). These resources include cooperative apartments, halfway houses, and psychosocial rehabilitation centers such as Fountain House and Thresholds (68). Such community support systems are in part a response to the progressive nuclearization of the family and are intended to provide the support that has been lost because of the dissolution of extended kinship networks or discharge from the hospital.

Unfortunately, community resources are still relatively scarce, they can accommodate only a small portion of potential clients, and they remain largely isolated and little known because most result from the efforts of one or two concerned, enthusiastic persons. Generally, they are a response of the private sector to failures of the medical and social welfare systems to provide adequately for the needs of patients. However, NIMH has recently funded 18 pilot demonstration community support programs.

The efficacy of these programs, beyond their humanitarian importance, remains largely untested. Although the efficacy of particular community supports (e.g., psychosocial rehabilitation centers) is not well established, there are data that suggest community support systems are effective and will therefore receive even greater emphasis in the next decade. Data from the International Pilot Study of Schizophrenia (69) are relevant to the issue of community support. This careful longitudinal research involved more than 1,000 patients in eight countries on admission to a hospital and 2 and 5 years later. They found, to everyone's surprise, that the outcomes of schizophrenic patients in developing countries (Nigeria, India, Colombia) were significantly better than those of patients in developed countries (United States, Russia, England,

Denmark, Czechoslovakia). Although this finding is open to a variety of interpretations, an explanation positing the presence of supportive extended kinship networks is consistent with the family organizations in these developing countries. A related explanation—that these relatively uncomplicated societies are less stressful to individuals—also fits the community support model. It has been shown for medical illness (70, 71) that social support protects against the development of illness and aids recovery when illness is related to life stress. Thus, one parsimonious explanation is that in developing countries, for whatever levels of stress occur there is greater protection available to individuals from their naturally occurring social support systems. This case is even more persuasive when taken in conjunction with two bodies of data from the United Kingdom which indicate that 1) schizophrenics experience greater life stress than others in the 3-week period before the onset of overt symptomatology (72), and 2) having more than 35 hours a week of face-to-face contact with hostile, critical, overinvolved parents or spouses is highly predictive of relapse among discharged schizophrenics, even when they are maintained on neuroleptic drugs (73).

In sum, there is a substantial body of data derived from several different perspectives indicating that social support systems, especially relationships outside the nuclear family unit, can serve as protective buffers for individuals exposed to stresses that can result in the development or exacerbation of schizophrenia.

Although they have not generally been conceptualized as community support systems, a variety of alternatives to hospitalization have been studied; these can be seen as providing support systems for individuals undergoing the severe personal distress and crisis that comes to be labeled schizophrenia. Stein and Test's training in community living (74), Langsley and associates' family crisis intervention (37), Pasamanick and associates' visiting nurse program (75), Sanders and associates' enablers program (76), Polak and Kirby's family foster care (77), Fairweather and associates' lodges (56), Mosher and Menn's Soteria program (78), and day-care centers (79, 80) are examples of the intentional provision of a support program in lieu of the support inherent in hospital care. The results of these divergent programs, used with a wide variety of patients, have been similar. Each study found that the vast majority of acutely disturbed schizophrenics, who would otherwise have been hospitalized, can be treated effectively and at lower cost in nonhospital settings if sufficient interpersonal support and protection are made available to them and to their caretakers (33).

What remains to be learned from these studies is a more refined definition of the specific and nonspecific ingredients in each program that result in optimal recovery. However, the uniformity of available results seems to warrant the more widespread implementation of such programs—especially in view of rapidly escalating hospital costs. Yet, with the exception of Fairweather and associates' lodges (56), this has not happened. The barriers to wider use are both conceptual, in that treating severely disturbed persons outside of hospitals is contrary to long-standing practice, and fiscal, in that third-party payers, including Medicaid, as a rule will not reimburse for nonhospital residential care. Thus, in addition to the further research needed, there is also a need for incentives to provide cost-effective alternatives to hospitalization and fiscal mechanisms that will support such alternatives adequately.

CONCLUSIONS

Perhaps the most important statement that can be made on the basis of this review of recent research on psychosocial treatments for schizophrenia is that we know more about their effectiveness than is generally acknowledged. Although critical, experimentally oriented researchers might disagree with this conclusion on methodologic grounds, we believe the consistency of the data about the effectiveness of psychosocial treatments supports this interpretation. It is noteworthy that the positive findings from controlled studies are most consistent for those treatments that involve extensive attention to the individual patient's social environment (i.e., non-hospital-based family therapy and various residential milieu therapies, including alternatives to hospitalization).

If these findings are considered in conjunction with the less methodologically rigorous evidence for the positive effects of support systems on outcome, it is tempting to conclude that the most effective types of psychosocial treatments for schizophrenia are those that provide the most comprehensive, corrective sustaining social support systems.

Although a great deal of research on these types of treatments is recommended, it does seem that based on this review, family therapy and a particular type of milieu treatment can be recommended for newly diagnosed schizophrenics. In addition, the more widespread implementation of various alternatives to hospitalization is supported by the available evidence. Finally, a specific behavior-change-oriented milieu approach to very chronic patients seems warranted by the studies we have reviewed.

Awareness and Disengagement in Cancer Patients

BY EDWARD GOTTHEIL, M.D., PH.D., WEALTHA C. MCGURN, R.M., M.S.N., PH.D., AND OTTO POLLAK, M.S.W., LL.D., PH.D.

The authors found that cancer patients (N=44) did not differ from patients with other chronic illnesses (N=27) with respect to awareness of their condition or ratings on an unobtrusive, nonverbal measure of disengagement. Cancer patients who were aware were more engaged than those who were not, but this was equally true for the noncancer patients. Awareness, for the cancer patients, was not associated with frequency of visiting or with living for a longer or shorter period than expected. There was a significant interaction, however, in that patients who were aware lived longer if they were engaged, whereas patients who were unaware lived longer if they were disengaged. Caution and judgment should be exercised in sharing information with terminally ill patients because awareness may be beneficial for some but not for all.

IN RECENT DECADES, many have come to believe that access to the information that one has a terminal condition, which approximates knowledge of one's diagnosis in people with cancer (1, 2), facilitates an acceptance of dying, improves the quality of life that still remains, and leads to a more peaceful and dignified death (1-8). Others believe that denial of one's condition, including denial of apparent physical deterioration, preserves hope and life. They suggest than an inability to maintain denial results in hopelessness, depression, and premature mortality (9-15).

Lacking a body of relevant experimental data, we are faced with a conflict in values. Is there or should there be a right to the truth about one's impending death? Is there or should there also be a right for an individual to refuse consciously or unconsciously to face such information or to avoid the question entirely? Should one provide information that has not been requested? Should one tell the truth if the truth may be harmful? Physicians must make these decisions daily. The immediate question is whether sharing such information will prove beneficial to patients, and in this regard there are few reliable guidelines to help physicians. Merely preserving life is no longer considered a satisfactory and sufficient criterion, and variables such as hope, the will to live, and the quality of life have not been readily amenable to objective investigation. Nevertheless, in a previous paper, we suggested that meaningful and measurable criteria could be developed to evaluate the consequences of awareness, such as the maintenance of communication channels, degree of disengagement, and actual length of life compared with expected length of life (16).

A continuing involvement in the world of people and things would appear to represent a more desirable attitude toward living than depression, "turning to the wall," and disengagement. Responding to external stimuli, retaining an interest in one's possessions and appearance, and keeping in touch with events are observable and quantifiable behaviors. An index of disengagement made up of such items would seem to be related to important aspects of the quality of life. Maintaining communications with family and friends is also generally considered to be desirable and beneficial. Although there are differing opinions about whether awareness or lack of awareness is more likely to encourage visiting, visiting patterns are observable, and few would disagree that visiting provides the patient with support and helps to preserve hope. Finally, there are many reports about patients who have given up and died sooner than expected or fought and lived longer than expected. To the extent that one's motivation and attitudes contribute to survival, an index of living longer than medically expected would seem to reflect not only extended existence but also hope and a will to continue living.

The main purpose of the present study was to compare cancer patients who were aware of their condition with those who were not with respect to 1) disengagement, 2) visiting patterns, and 3) living for a longer or shorter period than expected. Another purpose was to compare cancer and noncancer patients with respect to awareness and disengagement. A critical constraint on the design of the study was the neces-

sity to develop instruments and methods that were not intrusive so that the procedures would not alter the patients' state of awareness.

METHOD

Subjects

Two general medical floors serving patients of similar socioeconomic status were selected for the study. The majority of patients on these floors had diagnoses of cancer or of cardiovascular, renal, or neurologic disease. At the time our observations were made, there were 44 patients with malignancies and 27 with other diseases who met our criteria of being between the ages of 45 and 75, lucid, mobile, and able to move the head and all extremities. There was no significant difference in age between the cancer and noncancer patients.

Indices

Awareness. Judgments regarding awareness of diagnosis were categorized as follows:

1. Both patient and family know the diagnosis.
2. The patient but not the family knows the diagnosis.
3. The family but not the patient knows the diagnosis.
4. Neither the family nor the patient knows the diagnosis.

Although we could not question patients or family members without affecting their awareness, information could be obtained from attending physicians, house staff officers, or nurses. While physicians know what they have told the patient and/or the family, they might not know what has been retained or what the patient and family have told each other. House staff officers should be able to assess the "working knowledge" of the patient but often have little contact with the family. We expected the floor nurses, who spend more time with both patient and family, to provide the most useful judgments. In a pilot study, 41 patients were judged as to their state of awareness by their attending physicians, house staff officer, and two nurses. The judgments of the nurses did not differ significantly from those of the attending physicians or house staff officers, but the attending physicians and house staff did differ significantly from each other ($\chi^2=6.01$, $p<.05$). Furthermore, the judgments of the two nurses who had rated each of the 41 patients were highly consistent (90% agreement). In the current study, therefore, nurses' judgments were used to categorize the patients' state of awareness.

Actual/expected survival time. In "End Results in Cancer" (17), life expectancies after diagnosis are provided with reference to the patient's age and the type and site of the malignancy. The patients were compared in terms of actual versus expected length of life after diagnosis.

Disengagement. The Nonverbal Disengagement Index (appendix 1) was developed to assess an individual's involvement in the world of people and things without the need for interview data. The index includes the following 10 items, which are rated on 5-point scales from engagement to disengagement after a brief observation of the patient: orientation, posture, grooming, dress, personal effects, reaction 1, reaction 2, modesty, expression, and activity.

The reliability of the instrument was evaluated in several ways. In one pilot study, 15 observations were made of each of 63 patients over a 5-day period. Stability over observations was investigated by comparing scores obtained during even-numbered observations with those obtained during odd-numbered observation periods. The correlation was significant ($r=.69$, $p<.01$). Internal consistency was evaluated by comparing scores on each item with the total scores of the other 9 items. The correlations ranged from .34 to .74 (average=.52) and were all significant ($p<.01$). In addition, interrater agreement was evaluated in another pilot study in which two observers independently rated a sample of 40 patients. The ratings of the two observers did not differ in mean scores and were highly correlated ($r=.88$, $p<.01$).

Visiting. During a trial period it was found that nurses' judgments were consistent in categorizing visiting frequency as either none, rare, few, or many. Furthermore, the nurses appeared to have no difficulty in responding to the question.

Procedure

Observations for the Nonverbal Disengagement Index were made by one of the authors (W.C.M.) in the course of changing water carafes at the usual times: morning, afternoon, and evening. The procedure took approximately 30 seconds and scores were recorded on the answer sheets after the observer left the patient's room. Scoring required approximately 10 seconds and was unobtrusive because the large cart used to transport the carafes held much other paraphernalia. Three observations were made of each patient on 5 consecutive days, for a total of 15 observations. Patients who were not present for at least 8 observations (e.g., were out of the room for X rays or were discharged during the study) were not included in the analyses. Individual scores were averaged and converted to a distribution with a mean of 100 and a standard deviation of 10. The range of scores was from 80.7 to 127.6, and people with scores over 100 were considered engaged. For this group, disengagement scores were not significantly related to the ingestion of tranquilizers, antidepressants, sedatives, or analgesics.

Following the observation period, awareness and visiting ratings were obtained from the charge nurses. Information about the type and site of malignancy and the date of diagnosis was obtained from the charts or by contacting the patients' attending physicians.

TABLE 1
State of Awareness of Patients with Malignant and Nonmalignant Conditions

Awareness Category	Malignancy (N=44)		No Malignancy (N=27)	
	N	%	N	%
1 (patient and family)	27	61.4	20	74.1
2 (patient only)	0		0	
3 (family only)	12	27.3	2	7.4
4 (neither)	5	11.4	5	18.5

TABLE 2
Awareness and Disengagement of Patients with Malignant and Nonmalignant Conditions

State	Malignancy		No Malignancy	
	N	%	N	%
Aware				
Engaged	17	63	14	70
Disengaged	10	37	6	30
Unaware				
Engaged	5	29	2	29
Disengaged	12	71	5	71

TABLE 3
Relationship of Visit Frequency to Awareness and Disengagement in Cancer Patients

Visitors	Aware		Unaware	
	Engaged	Disengaged	Engaged	Disengaged
Rare or none	1	6	1	3
Few	5	0	1	6
Many	4	1	2	0
Total	10	7	4	9

TABLE 4
Relationship of Awareness and Disengagement to Survival Time After Diagnosis

State	Lived Longer		Died Sooner	
	N	%	N	%
Aware				
Engaged	7	85.7	10	52.6
Disengaged	1	14.3	9	47.4
Unaware				
Engaged	1	12.5	4	50.0
Disengaged	8	87.5	4	50.0

RESULTS

The numbers of patients with malignant and nonmalignant conditions who were rated as falling into the four categories of awareness are given in table 1. In most instances, both patients and families were aware of the diagnosis. There were no cases in which the patient was aware and the family was not. Subsequent analyses were based on patients' awareness (categories 1 and 2) or unawareness (categories 3 and 4). While cancer patients tended to be more highly represented than noncancer patients in category 3 (family aware and patient unaware), the overall distributions by state of awareness for patients with malignant and nonmalignant conditions were not significantly different. Similarly, there was no significant difference between the proportions of cancer and noncancer patients who were disengaged (50% and 41%, respectively, see table 2).

A significant difference was found when individuals with malignant and nonmalignant conditions were compared with respect to both awareness and engagement ($\chi^2=9.40$, $p<.05$). As indicated in table 2, awareness was associated with engagement in both cancer and noncancer patients, but there was little difference in the extent of this relationship attributable to diagnosis.

Data on frequency of visiting by families and friends were available for only 30 of the patients with malignant conditions because this variable was introduced later in the study (see table 3). Visiting frequency was not found to be associated with state of awareness but was associated with engagement ($\chi^2=7.75$, $p<.05$). Engaged individuals were visited more frequently than those who were disengaged.

The patients with malignancies were followed by examining the records or contacting their attending physicians for 3 years, at which time 40 of the 44 had died. Seventeen had lived longer than expected and 27 died sooner than expected. The group lived an average of 1.2 years less than expected. This is probably attributable to 1) four patients who were still living and could contribute to increasing the average, and 2) the sample being composed of patients who were already in trouble and had been referred to a university hospital. The actual length of life after diagnosis correlated significantly with the actuarial expectancies ($r=.38$, $p<.05$). Of the 27 patients who were aware of their diagnosis, 19 (70.4%) died sooner than expected as compared to 8 of the 17 (47.1%) who were unaware (table 4), but this difference was not statistically significant. Similarly, 14 of the 22 patients (63.6%) who were engaged died sooner than expected as compared to 13 of the 22 (59.1%) who were disengaged, a nonsignificant difference.

A significant relationship was found when patients who lived longer or died sooner than expected were compared with respect to both awareness and disengagement ($\chi^2=9.74$, $p<.05$). The major contribution to this finding apparently was made by the interaction of awareness and disengagement in the "lived longer" category. Patients who were aware lived longer if they were engaged, while those who were unaware lived longer if disengaged. Interestingly, dying sooner than expected was not significantly associated with any of the combinations of awareness and engagement.

DISCUSSION

While there are strong opinions about the effects of telling terminally ill patients about their condition, there have been few experimental studies to support these positions because of the difficulty involved in operationalizing criteria such as hope, will to live, and quality of life. In developing the measures of awareness, disengagement, visiting, and length of life versus expected length of life for use in this study, another difficulty was the requirement that the methods be unobtrusive so that they would not affect the state of awareness of the patients and family members.

We first compared our group of cancer patients with a matched group of noncancer patients from the same medical floors and found no significant differences in awareness or disengagement. Of course, the noncancer patients also had chronic illnesses and some were terminal. Nevertheless, in this hospital for these patients the diagnosis of cancer did not affect disengagement or awareness significantly more than did other diagnoses.

Cancer patients who were aware were more engaged than those who were unaware, but this was also true for the noncancer patients. Awareness of a diagnosis of cancer appeared to have no greater impact on disengagement than awareness of other diagnoses. It may be that instead of assessing the effects of awareness on disengagement we were really observing the effects of engagement on awareness. Engaged individuals are more interested in the world and their surroundings and may therefore ask more questions and receive more information. To resolve this question we would need to conduct a longitudinal study to learn whether engaged people are told their diagnoses more often than disengaged patients and then to note how a change in awareness affects the state of engagement.

Awareness was not related to frequency of visits by family and friends, whereas engagement was significantly related to visiting. Engaged people were visited more often than those who were disengaged.

With respect to the longevity of cancer patients, neither awareness nor disengagement was significantly related to actual versus expected length of life after diagnosis. However, there was a significant interaction. Patients who were aware lived longer if they were engaged, whereas patients who were unaware lived longer if they were disengaged. It may be that awareness is more beneficial for those patients who are engaged and interested and possibly ask more questions, whereas disengaged individuals may do better if they are not given more information than they request. We did find that the actual time lived past diagnosis correlated significantly with statistically derived life expectancies.

Our study does not provide answers as to who should be told, when they should be told, what they should be told, how they should be told, or by whom. More research is required. We have demonstrated that questions such as these can be experimentally investigated and evaluated in relation to meaningful and measurable criteria. Until this research is done, caution and judgment should be exercised in sharing information with terminally ill patients. Cancer patients who were aware of their diagnoses did not have more visitors and did not live longer than those who were unaware. With respect to engagement, awareness of cancer did not appear to have a greater effect than awareness of other diagnoses. Since awareness may be beneficial for some patients but not for all, each patient should be evaluated as carefully as possible and treated with judgment, respect, and sensitivity to his or her individual needs, fears, strengths, and anxieties.

APPENDIX 1
Nonverbal Disengagement Index[1]

I. *Dimensions*
A. *Orientation:* the direction in which the patient is facing

[1]Instructions for completing the Index are as follows: "Choose the description under each heading that best fits the patient. Check the box on the score sheet that corresponds with the description you choose."

1. To observer or other person (including talking on the phone)
2. To object requiring attention or activity (tray, bathing, reading, etc.)
3. Neutral
4. To object with no activity occurring, blank space, or wall
5. Seems turned away from any potential stimulus to activity or attention (such as turning back on person talking, pretending sleep, or having curtains pulled around the bed)

B. *Posture:* the patient's position in space
1. Movement of person or extremities in or out of bed
2. In bed, nonreclining
3. In bed, reclining
4. Propped in chair or bed—inactive
5. Lying in bed in fetal, closed, or rigid position

C. *Grooming*
1. Well groomed
2. —
3. Clean but not neat (disheveled, unshaven, or clothes rumpled)
4. —
5. Not groomed

D. *Dress*
1. Wears his own clothing
2. —
3. Wears a combination of his own and hospital clothing
4. —
5. Does not use any personal clothing

E. *Personal effects in the room:* includes everything from having the TV service to grooming articles, radios, food, or pictures brought from home and gifts, flowers, or cards sent by others.[2]
1. Family pictures, favorite pillows, or work brought from home
2. Hobby objects (including nonfiction books, food requested from home)
3. Light reading materials, radio, or TV service
4. Flowers, cards, or gifts and grooming objects
5. No personal objects

F. *Reaction 1:* patient reactions when you do not initiate interaction
1. Initiates personal interaction
2. Makes a request of a functional nature or a comment related to something about his care
3. Reacts with social amenities ("please," "thanks," etc.); relatively noninteractive
4. Glances at you—reactions tend to be noncommittal
5. Turns away or ignores you

G. *Reaction 2:* patient's reactions when you have smiled at him or initiated interaction verbally
1. Interacts with you verbally
2. Reacts with a bare minimum of what is socially acceptable
3. Smiles, carries out social amenities, but does not converse
4. Glances, makes noncommittal responses
5. Gives no acknowledgment of you or turns away

H. *Modesty*
1. Dressed as though he were in a hotel—very modest
2. More casual but appropriately dressed
3. Mixed impression
4. Partially exposed through light clothing, etc.
5. Exposes breasts, genitals, or buttocks

I. *Expression*
1. Emotionally expressive

Psychiatric Combat Reactions During the Yom Kippur War

BY ITZHAK LEVAV, M.D., HAIM GREENFELD, AND ELI BARUCH, M.D.

The authors explore the stress of war by reporting some selected epidemiological aspects of the psychiatric combat reactions among Israeli troops during a period of intensive hostilities in the Yom Kippur War of 1973. They examined the distribution of these casualties according to intensity of fire, age, rank, sociopsychological grading, and military assignment and measured treatment outcome at the end of the war and 18 months later.

WARS HAVE BEEN and, regrettably, still are laboratories in which the effect of major stressors can be investigated (1). Glass (2) stated that "wars provide unusual opportunities for learning, firsthand, the problem of man's adaptation under difficult and changing circumstances."

The stress of war is the theme of this report. We will deal with selected psychiatric epidemiological aspects of the casualties during an active fighting period in the Yom Kippur War of 1973. We feel that the results of this inquiry contribute to the growing body of literature on stress, which encompasses natural and man-made disasters (3) at one extreme and the general spectrum of less exceptional life events (4) at the other.

We have made use of the concept of the epidemiological triangle of agent (intensity of fire), host (age, rank, and sociopsychological grading), and environment (Army corps and military assignment) to guide the presentation of our data. We feel that this model helps coalesce findings that have developed somewhat apart in the literature (5).

The different labels given to the psychopathology related to war stress epitomize the opposing stands regarding its etiology and treatment. In a review of the experience accrued during World War II and the Korean conflict (5), Glass stated that the early label of "psychoneurosis" has "implications of unresolved intrapsychic conflict from which symptoms are unsuccessfully derived" but that war studies have "caused awareness that social and situational determinants of behavior are more important than the assets and liabilities of individuals involved in coping with war stress and strain." The literature has, in part, adopted opposing positions, addressing itself either to the premorbid personality of the soldier who suffers psychiatric combat reaction (host) or to the military factors related to the rate of casualties (agent/environment). We believe that the data presented here will lead to the adoption of an eclectic stand.

METHOD

The time span covered by the study was a period of active warfare characterized by a large number of casualties in all of the troops involved in the fighting. Case identification and time of onset of the combat reaction were based on the review of the record of each soldier evacuated to treatment centers away from the firing line. The group studied was composed of soldiers suffering from acute combat reactions who were treated away from the front line by specialized Army personnel. The study group did not include soldiers whose combat reactions were treated in their units or at the battalion level by Army medical teams or those whose emotional reaction accompanied a physical injury.

The diagnoses were independently made by two of us (I.L. and H.G.). In only a few of the cases (less than 2%) were there discrepant diagnoses; these were settled by agreement.

Additional information on each soldier was obtained from his personal military file. This information included educational level, ethnic affiliation, and previous military assignments as well as a sociopsychological grading that provided an indication of the individual's intelligence and personality features. The sociopsychological grading, which represents the measurements of one element of the epidemiological triangle (host), consists of education, command of the language, general abilities, and intelligence. All these are regarded as measures of the intellectual function of the individual. Personality features were determined by such measures as sociability, punctuality, and identification with the Army (6). Each file also included a mili-

Modified version of a paper presented at the VI World Congress of Psychiatry, Honolulu, Hawaii, Aug. 28-Sept. 3, 1977. Received Oct. 12, 1977; revised May 26, 1978; accepted July 18, 1978.

Dr. Levav is Lecturer, Department of Social Medicine, Hadassah Medical Organization and the Hebrew University-Hadassah Medical School, P.O.B. 1172, Jerusalem, Israel. Haim Greenfeld is a Captain and, at the time this paper was submitted, Dr. Baruch was a Lieutenant Colonel, Mental Health Services, Israel Defense Forces, Tel Hashomer, Israel. Dr. Baruch is now Director, Mental Health Services, Ministry of Health, Jerusalem, Israel.

The authors acknowledge the assistance of H. Bardin, M.E., Capt. Y. Sudri, Dr. E. Bar-Natau, and Dr. N. Egoz. The Army mental health teams provided the raw data that served as the basis for this report.

tary-psychiatric grading—an overall clinical evaluation of the type of psychopathology present and an appraisal of the disability level of the individual relative to his role in the Army.

Data on changes that took place in the military-psychiatric grading after intervention by mental health personnel were also available. These gradings were compared with those made at follow-up 18 months after the cessation of hostilities. Information was also obtained on the few cases in which changes had taken place at a time other than at follow-up but after 18 months.

The study group was compared with soldiers who had been in the theater of war and who had suffered nonpsychiatric injuries. The latter group, which was used for comparison rather than as a true control group, resembled the study group in type of military assignment—active participation in battle. The essential difference between the groups was in the type of pathology that prompted removal from the firing line.

CASE REPORTS

Case 1. A soldier was brought to the field hospital in a state of clouding of consciousness. During the course of abreactive treatment the soldier described having experienced the following traumatic events: after a number of days of continuous fighting, with almost no food or sleep, his unit suffered heavy bombing from the air. After losing consciousness he awakened in a ditch, where another unit found him. He was then transferred to the medical station for treatment. However, this station was also bombed. He again passed out and when he awakened found himself in a field hospital. The hospital personnel gave him a diagnosis of gross stress reaction, conversion type, and recommended that he be kept for a short rest and then returned to his original unit.

Case 2. A soldier was transferred to a general hospital in the rear, where he was interviewed by a psychologist. He had been evacuated from his unit because he lost consciousness after a shell hit his tank. A fellow tankman with whom he had served for about 10 years was killed in that action. The hospital record indicated that while in the hospital he still suffered from dizziness, pain and pressure in his head, insomnia, tension, and poor concentration and was totally inactive, lying in bed most of the time.

FINDINGS

Agent Data

(Because of security considerations the data presented do not include rates or the number of soldiers in each group used as bases for percentages. Figure 1 has a schematic format for the same reason. The tests of significance were based on the original numbers, which are classified information.)

The data on the agent (intensity of warfare or fire) in the epidemiological triangle were measured by the number of soldiers wounded in action, a criterion suggested by Glass (7) on the basis of his studies during World War II. Figure 1 shows that the shape of the curve depicting the frequency distribution of psychiatric combat reactions is quite similar to that of the physical casualties except for a short time lag between the two.

FIGURE 1
Percent of Subjects Involved in Physical (Wounded) and Psychiatric Casualties by Day of Combat

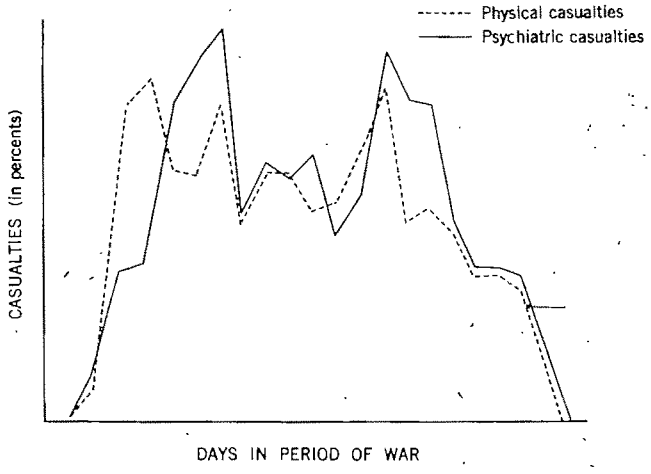

TABLE 1
Number of Physical (Dead and Wounded) and Psychiatric Casualties

Army Unit	Deaths	Wounded	Psychiatric Casualties
A	5	30	17
B	2	15	13
C	0	7	4
D	0	1	1
E	0	2	0

A closer look at the casualties of five Army units provides a further corroboration of this relationship. Table 1 shows that the higher the number of dead and wounded the higher the number of psychiatric combat reactions. In other words, the more intense the fire the higher the number of psychiatric casualties.

Environmental Data

Military assignment essentially determines such factors as whether the soldier is in a passive or active role in the face of danger, whether he is alone or in a group, and whether he strongly or loosely identifies with his unit. As an illustration, table 2 shows a comparison of three major military assignments. The fighting group includes soldiers whose primary duty was to actively participate in combat. The logistic group includes soldiers whose primary task was to provide logistic support for the fighting group. The services group includes soldiers in the service units posted either close to or relatively far away from the firing line. A comparison of the distribution of the psychiatric casualties and the physically injured in combat or, rather, the examina-

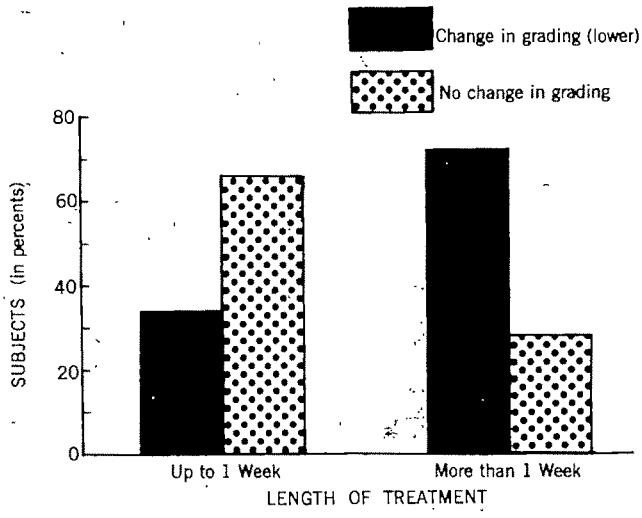
Distribution of Psychiatric and Physical (Wounded) Casualties by Rank, Age, and Sociopsychological Grading

Characteristic	Percent of Psychiatric Casualties	Percent of Physical Casualties	Ratio of Psychiatric to Physical Casualties
Rank[a]			
Nonofficers with low or intermediate rank	91.4	79.4	1.2
Nonofficers with high rank	3.4	4.6	0.7
Officers	3.0	16.0	0.2
Age[b]			
Up to 18[c]	4.8	0.02	240.0
19-24	31.3	50.6	0.6
25-29	38.9	28.7	1.4
30 and older	23.2	20.8	1.1
Sociopsychological grading[d]			
Low	15.5	8.4	1.9
Middle	32.8	16.8	2.0
High	50.9	75.0	0.7

[a]The rank of 2.2% of the soldiers was unknown.
[b]The age of 1.8% of the soldiers was unknown.
[c]The number of soldiers in this age group was so small that I was advised to drop this category altogether.
[d]The grading of .8% of the soldiers was unknown.



tion of the ratios observed by dividing the former by the latter shows that a soldier in a nonfighting assignment was in a relatively high risk group for war stress. This difference was statistically significant (χ^2=256.85, df=2, p<.001).

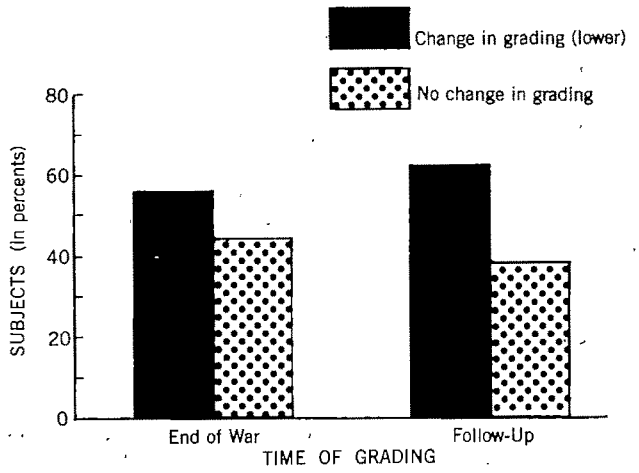
Table 2 also shows a comparison of two Army units with different assignments. We built a control for age and, to a limited extent, personality factors into this comparison, and the results are identical to those for the whole Army. Soldiers in the nonfighting groups had significantly more psychiatric casualties (χ^2=48.62, df=2, p<.001).

Host Data

Military rank is a complex concept that encompasses personality features, abilities, degree of responsibility, and relationships with other men. To be an officer usually implies, among other things, that one is intelligent and well educated, has a higher set of norms, and is able to provide leadership. In the Israeli Army, the officer usually leads his unit into battle; thus, he places himself in a most vulnerable position. The comparison of physical casualties and psychiatric combat reactions is of interest for the elucidation of the role played by the host in the epidemiological triangle. The data in table 3 show that officers were five times less vulnerable to war stress; the inverse was true in the lowest rank. This difference was significant (χ^2=134.20, df=2, p<.001).

FIGURE 2
Percent of Subjects Receiving Changes in Military-Psychiatric Grading Before and After 1 Week of Treatment

A comparison of both groups of casualties by age shows that the youngest soldiers and those 25 to 29 years old were particularly vulnerable to war stress (see table 3). This difference was significant (χ^2=248.42, df=2, p<.002). Table 3 also shows that men with lower sociopsychological gradings seemed to have been at significantly higher risk to develop war stress (χ^2=29.32, df=2, p<.001).



Other things being equal, the ratios of psychiatric to physical casualties show the greater role of host and environmental factors in contrast to the agent as a factor, as shown in figure 1 and table 1.

Treatment Outcome

Treatment outcome was measured in terms of the change that took place in the military-psychiatric grading of the soldier. Since guidelines for treatment have been well established in the literature and there is universal agreement as to their benefit (7), we examined the data to see whether further insights might be gained. We found that treatment lasting more than 1 week brought about changes in the military-psychiatric grading in more than 50% of the studied population: the longer the treatment the higher the likelihood the soldier was given a lower grading (see figure 2).

Of the variables investigated, the sociopsychologi-

FIGURE 3
Percent of Subjects Receiving Changes in Military-Psychiatric Grading by the End of the War and at 18-Month Follow-Up

cal grading was the only one found to be highly correlated with the military-psychiatric grading (Kendall's Tau B=.240, p=.002). The lower the sociopsychological grading the lower the military-psychiatric grading, indicating that personality factors acted in the rate of recovery.

By the end of the war, 55.1% of the psychiatric casualties had received gradings lower than the ones they had had at the outset of hostilities. Of these, 17.4% were regarded as temporarily or definitely (1.2%) unfit for further military duties. The status of the group as a whole did not tend to improve at 18-month follow-up. On the contrary, new cases (6%) were eventually added to the group whose profiles were lowered (see figure 3). Again, the sociopsychological grading was correlated with the military-psychiatric grading at follow-up (Kendall's Tau B=.197, p=.01).

DISCUSSION

The concept of combat psychiatric reactions as used in this study comprises all behavioral manifestations related to the stress of war, including psychomotor and sensorial manifestions. However, no claim for completeness can be made because it is likely that such allied psychiatric problems as self-inflicted wounds, illegal avoidance of combat, and passive participation in battle (7) were not covered because of the sources of data used.

The psychiatric casualties included in this report were only those treated at the rear. However, in view of administrative directives in force at the time, it is reasonable to assume that the study population comprises almost all of the casualties because soldiers who required any intervention by a physician were evacuated. (Interviews held with physicians who staffed the medical outfits of some of the battalions most actively engaged in combat confirmed the fact that only a small minority of soldiers were treated at the front.)

In a study of Swedish soldiers who were involved in combat in the Congo (Zaire) in 1961 as members of the United Nation Forces (8), Kettner compared 35 men who broke down from "combat exhaustion" with 35 control subjects who were "serving at the same time and under comparable conditions in the Congo but did not break down." Despite the neatness of his investigation, however, Kettner's number of cases was small. Furthermore, since these soldiers belonged to a selective force, their situation rendered the study less comparable to those of other wars, e.g., World War II (9), or to most armies that use different criteria for recruitment than does the United Nations. Therefore, despite the progress made as a result of Kettner's study the problem of control groups in studies of war stress remains open.

The group of physical casualties used for comparison in our study does not constitute a control group in the strict sense of the term (10) because of the interrelationship between the physical and psychiatric casualties. However, constraints arising out of the realities of war demand a softer stand that allows for the argument that the group selected is potentially useful for the comparison of such variables as rank because men serving in the same units were subjected to identical fire conditions.

The epidemiological triangle shows the factors related to the agent, the host, and the environment were involved in whether or not a soldier had psychiatric difficulties. In fact, a composite profile of the man at risk could be built: given a day of intense fire, the youngest soldier or the one older than 25, of low military rank and with a low sociopsychological grading, participating in combat in logistic or service units, was relatively more vulnerable to stress.

We have not exhausted all of the factors likely to be linked to combat psychopathology (11). In fact, we have restricted ourselves to only a few of them. It is of interest to consider that vulnerability increases in an inverse relationship to the scores obtained on tests of certain personality features (e.g., punctuality and sociability) and measures of intelligence. These results are comparable to those suggested by Glass and associates (12) in studies of prediction of performance in the military and, to some extent, to Lazarus' on coping behavior according to personality style (13). It is worth noting that the factors cited above operate even when unfit men have already been screened out at recruitment. These factors were not found in Kettner's very selective troops (8), but it was possible to find these factors in our study because of the wider base of the Israeli Army.

Another factor worth emphasizing is the protective effect of the soldier's role: adaptation to danger through activity seems to diminish psychiatric risk. However, it should be noted that the way we measured role—by military assignment—includes a consideration of the availability of support through imme-

diate interaction with other soldiers. A relatively low proportion of officers broke down, but personality factors and intelligence also played a part in this finding. Not all men are equally vulnerable to stress (fire, in this case). Both predisposition and environmental factors account for breakdown in combat. (Unfortunately, we did not analyze their relative weight.)

Our data might seem to indicate that a critical period of up to 1 week for the treatment of combat reactions establishes a dividing line between good and poor outcome. Of course, the point could be made that the length of treatment was primarily a function of the type and severity of the psychopathology present and not a result of the use of a criterion based on management procedures. We tend to give a greater weight to the latter argument, at least as far as the treatment of the psychiatric casualties in the Yom Kippur War is concerned. A number of our case records showed that although a recommendation was made that a soldier be returned to his unit, the soldier was admitted to a second treatment setting. Therefore, conditions other than those based on psychopathology might have led to a lower military-psychiatric grading. We feel that it would be advisable to add another criterion, brevity, to the three already well established in the literature—immediacy, proximity, and expectancy (14)—to assure satisfactory outcome.

Intense stress leaves psychological scars that cause impaired functioning (15–17). On the basis of a 1-year follow-up study of 17 soldiers (of a total group of 24), Merbaum (18) observed "a chilling picture of the profoundly debilitating effects of [war] stress on future social and emotional adjustment."

The data presented here show that a year and a half after the end of hostilities the majority of the psychiatric casualties were judged unable to function in the military at their prewar level. Admittedly, these data were based on a follow-up that was not designed with the rigor of a research undertaking. Thus, spurious factors—such as the wish of the examining psychiatrist to spare the soldier return to a highly stressing situation, a likelihood to be reckoned with in a country that is still at war with its neighbors, or even the knowledge that the soldier broke down—might have limited the objectivity of the assessment. On the other hand, each soldier was seen at follow-up by more than one psychiatrist, which could have reduced the bias. The high correlation found between personality—measured in terms of sociopsychological grading—and psychiatric difficulties might suggest that not all of the results were in the eyes of the beholder but indicated the true status of the soldier. We could then assume that war stress produces not only acute but also chronic psychiatric disability.

The Myth of the Alliance with Borderline Patients

BY GERALD ADLER, M.D.

The author questions the concept of a therapeutic alliance in the psychotherapy of patients with borderline and narcissistic personality disorders. The motivating elements in their treatment are the emerging, sustaining transferences, which also allow the patients to appreciate the real qualities of their therapist. As they internalize aspects of their interactions with the therapist, including the therapist's real characteristics that are lacking in themselves, the patients gradually develop the capacity to work collaboratively with him or her. When a solid therapeutic alliance is established, the patients have reached a neurotic level of functioning.

BORDERLINE PATIENTS present serious difficulties to the therapist who wishes to engage them in collaborative psychotherapeutic work. Intrinsic to the problems of these patients is an inability to establish and maintain a therapeutic alliance. The nature of their often overwhelming feelings that emerge during psychotherapy can rapidly disrupt a tentative alliance as well as the continuation of therapy itself. This paper will address the issues of difficulties in alliance formation with borderline patients, present an understanding of the developmental, structural, and defensive aspects of these patients relevant to alliance problems, and stress the aspects of the real and transference relationship between patient and therapist that facilitate or hinder the continuance of the developing fragile alliance with borderline patients.

CORE BORDERLINE ISSUES

The state of the borderline patient's ego development, the quality of his or her object relationships, and the instability of a cohesive self set the stage for complex problems in psychotherapeutic work with them. When these patients are distressed enough to seek or accept treatment, they have regressed to a position in which life and death issues feel, and often are, paramount (1, 2). The usual precipitants involve the loss of a relationship that has offered a feeling of holding or togetherness; this loss has often occurred through the patient's escalating demands for support and sustenance, which are part of the borderline regression. This regression, with its intensified feelings of aloneness and abandonment, is at the core of the borderline problem. The patients' vulnerability stems from a failure to internalize a soothing, dependable, anxiety-mediating relationship (3) that usually develops from adequate experiences of "good-enough mothering" in childhood (4). Often these feelings can also be traced back to the maternal failures occurring between ages one and two, especially at the rapprochement subphase of Mahler's schemata (5) of separation-individuation.

Although it is an obvious oversimplification to ascribe an adult disorder to a specific failure of a childhood developmental phase, the behavior of the adult borderline patient in therapy can be more readily understood by cautious formulation and use of such models. The end result in the adult borderline is an inability to depend on internal resources for soothing and self-esteem and a concomitant inability to trust the external environment to provide what is missing within the person. When the primitive defenses of borderline persons become manifest through splitting, projective identification, denial, primitive idealization, and devaluation, as defined by Kernberg (6), it is extremely difficult for them to make appropriate use of people in their lives. Their allies may take on repudiated aspects of themselves and lose their sustaining or supporting roles.

As part of this emerging regressed state, borderline patients become increasingly in touch with their envy and rage (6), intensifying their sense of aloneness and abandonment. Their anger is particularly devastating to them, since it is experienced as destructive and often annihilatory in its most extreme form. This murderously felt anger propels the borderlines' regression to painful aloneness by triggering a specific aspect of their vulnerability: a loss of evocative memory capacity (3). As defined by Piaget (7) and Fraiberg (8), the capacity for object permanence (evocative memory

Revised version of a paper presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8–12, 1978. Received April 24, 1978; revised Sept. 11, 1978; accepted Oct. 17, 1978.

capacity) follows a developmental line that gradually allows the child to have a sustained memory of an object even when the object is absent. This capacity is not attained before 18 months of age and at first is vulnerable to regression to only recognition memory, i.e., the need to have the object repeatedly and frequently present in order to remember it. Once evocative memory capacity is solidly attained, the child has a concept of object permanence. This concept of object permanence gives the child the increasing ability to use internalized aspects of important people as part of himself or herself.

Borderline patients have not achieved a stable evocative memory capacity. When stressed by their mounting rage, they can readily regress to recognition memory capacity or even earlier, i.e., they lose the ability to have sustaining memories and fantasies of important people, intensifying their sense of painful aloneness and abandonment. In psychotherapy the patient's loss of evocative memory capacity is accompanied by his or her feeling that the therapist does not exist or has been destroyed.

THE NARCISSISTIC PERSONALITY-BORDERLINE CONTINUUM

Patients with narcissistic personality disorders, in contrast to borderline patients, do not have the latter's evocative memory vulnerability. In fact, the stability of the narcissistic or self-object transferences that narcissistic personalities establish is a major way of distinguishing them from borderlines. If the mirror and idealizing transferences that Kohut (9, 10) defined as diagnostic of narcissistic personality disorders are allowed to emerge without the therapist's interference in the countertransference, they are a manifestation of the patient's capacity to use the therapist in a new and useful way—as a self-object. The self-object concept defines the patient as requiring a relationship with the therapist of differing degrees of merger on a mirroring and idealization pathway. In this self-object relationship, the therapist performs certain fantasied and/or real functions that the patient feels are missing in himself or herself. When these self-object transferences emerge and are allowed to flourish, there is a sense of stability in the treatment that only momentarily breaks down in a fragmentation manifested by, e.g., transient hypochondriasis or aloof arrogance. This regression may appear when unbearable present or earlier feelings emerge or because of empathic failures of the therapist.

In contrast to this relative stability, the appearance of intense feelings in the borderline patient, for example, rage and envy (6), leads to a much more extreme fragmentation process. This process can result in the borderline patient's desperate emptiness and aloneness as part of his or her regression from evocative memory achievement and the self-object transference cohesiveness.

THE NATURE OF THE ALLIANCE WITH PRIMITIVE PATIENTS

The narcissistic personality-borderline continuum is important in understanding the nature of the motivating forces in the treatment and in defining issues of transference, therapeutic alliance, and real relationship with the therapist. In clinical work with borderline patients, we are frequently impressed with the rapid breakdown of what seems to be a tenuous, or sometimes even more solid, alliance. The "alliance" can disappear, and desperate borderline aloneness can emerge when unbearable affects appear in the therapy or when the therapist makes a response that is unempathic or perhaps incorrect. When we examine the narcissistic personality disorders with their stable self-object transferences, we can ask whether a therapeutic alliance exists or whether these primitive transferences themselves allow the patient to be sustained in the treatment. Although we invoke concepts of alliance and make statements about building alliance, it seems probable that the empathic optimal support and frustration offered by the therapist provide the empathic framework that the patient needs in order to sustain himself or herself with a self-object transference; the therapist can mistake this stable transference for an alliance.

It is often through the failure of our therapeutic work that we can clarify distinctions that were previously obscure. A case report can help to illustrate the absence of an alliance with a patient based on the failure to establish a sustaining self-object transference.

CASE REPORT

A 35-year-old single woman who sought therapy for chronic depression and inability to maintain relationships with men was regarded by both her therapist and his supervisor as someone with a hysterical character problem. After nearly 1 year of twice-weekly psychotherapy, the patient remained essentially unchanged and felt that she was making little progress. The therapist focused his work on her disappointment in her relationship with her father and competitive feelings toward her mother. He also stressed the collaborative nature of their work and emphasized frequently that the two of them were looking at or could look at certain issues and feelings together.

Following one of these exhortations about collaboration after approximately 1 year of therapy, the patient looked her therapist squarely in the eye and said, "Don't give me any more of that 'we' crap!" Although the therapist was momentarily stunned, he had no adequate response or explanation. It was only after careful review of his work with the patient that he concluded that he had been treating someone with a narcissistic personality disorder as a person with a neurotic character problem. His lack of understanding of the nature of the patient's despair and developmental difficulties was perceived by the patient as the therapist's empathic failure. Under those circumstances there was little to sustain the patient except for her perception that the therapist was occa-

sionally emphatically correct and struggled to understand her; however, nothing suggesting a therapeutic alliance was ever present with her.

TRANSFERENCE OR ALLIANCE

My review of the treatment of primitive patients, studied both through supervision of trainees and through conducting intensive psychotherapy, supports the hypothesis that the "we" invoked by the therapist often makes the therapist more comfortable but is effective only when it coincides with the patient's feeling sustained through a self-object transference. The patient usually does not experience the working collaboration; instead, he or she is held in the therapy by feeling supported, soothed, and understood.

At the beginning of the therapeutic process, when the patient's difficulties are clearly borderline with painful aloneness and loss of evocative memory capacity as primary problems, the therapist's main focus is on understanding the regression and the ultimate reestablishment of a holding environment and sustaining self-object transferences. Understanding the reasons for the patient's regression includes assessing whether unbearable affects, especially rage, envy, and disappointments, arose in the therapy related to the therapist, past figures, or people in the patient's current life. Based on this understanding and the awareness of the borderline patient's increased vulnerability when he or she transiently loses evocative memory capacity, the therapist takes appropriate steps to help the patient. These may include clarification and interpretation of the issues leading to the regression from evocative memory capacity, confrontation of the patient's avoidance mechanisms related to his or her ignoring real dangers to self-survival, and the therapist's availability and existence. As the therapist confronts the patient with his or her existence, which the patient cannot experience during this time, the therapist may offer extra appointments and opportunities for telephone contact to reestablish that the therapist does indeed exist, care, and is available for the patient (11). The therapist also balances his or her availability with the realistic limits of his or her own capacity to give and sustain. Thus hospitalization becomes an alternative when the therapist's appropriate help is insufficient.

When successful, these therapist activities demonstrate the therapist's existence, caring, commitment, and willingness to work hard with the patient. They also reestablish the holding, sustaining self-object transferences. However, they do not establish a therapeutic alliance, only the self-object precursors, which ultimately can be internalized slowly as the primitive transferences are resolved and neurotic transferences become more solidly established. At the point that the patient is capable of a solid therapeutic alliance, that patient no longer has a borderline or narcissistic personality disorder; in fact, he or she is well within the neurotic spectrum and approaching the end of therapy.

While borderline issues remain paramount, the tenuous and fluctuating therapeutic alliance with these patients can be monitored by the therapist's constant evaluation of the patient's needs for holding and support on the one hand, and capacity to bear frustration and face his or her disappointments and rage on the other hand. The empathic therapist titrates his or her responses based on an assessment of the patient's current capacities and vulnerabilities. The awareness that the inevitable empathic failures of all therapists will lead to episodes of the patient's feeling intense aloneness and abandonment provides the therapist with opportunities to clarify with the patient the nature of his or her vulnerability. Through this activity and support, the regressions that occur during psychotherpy with borderlines can most often be confined to the therapy session.

Over time, the patient learns that the therapist is a dependable person who can understand and bear the patient's transference distortions and exquisite vulnerability to regress whenever intense feelings emerge in his or her life and in therapy. With repeated episodes, the patient's regression becomes less intense because the repeated regressive episodes and their therapeutic utilization lead to the internalization of the self-object function and to structure formation. The consequent developing capacity to feel soothed and held while apart from the therapist, which includes the capacity to evoke the memory of the therapist between sessions, goes hand in hand with the development of higher level defenses, including the healing of splitting and the capacity to tolerate anger, closeness, and aloneness.

TRANSFERENCE, REAL RELATIONSHIP, AND ALLIANCE

In discussions of psychotherapeutic work with primitive patients, we often hear that the real relationship between patient and therapist is particularly important. The real relationship is rarely defined but is sometimes equated with the therapist's revealing much about himself or herself and his or her life and background (12). In the context of the present paper, we have the opportunity to explore the nature of the patient's real relationship with the therapist and its relevance to the discussion of the therapeutic alliance and sustaining primitive transferences.

Clinically, we have examples of therapists who reveal much about themselves to their patients yet find that their patients are stuck in a regressive impasse (12). It is also not unusual for primitive patients who know many facts about their therapist to say that they really do not *know* their therapist. Exploration of these statements often clarifies that these patients do not see others as separate from themselves; when they are not in a relationship in which they are partially fused to or merged with another person, they feel empty, fragmented, alone, and uncertain about who they are and

who the other person is. However, when they feel sustained in a relationship that offers them the degree and kind of merger or idealization experience they require, they feel whole and do not raise questions about not knowing the other person. Thus, when sustained in a self-object kind of relationship, they feel complete and do not question the reality of the other person when that person is part of themselves.

Paradoxically, when these patients are sustained in the stability of a self-object transference, they begin to develop the capacity to observe and appreciate the real qualities of the person they simultaneously use as a self-object. This capacity to see the real or objective qualities of people increases as they gradually internalize functions from the self-object that are missing aspects of their own ego and self. Finally, when they are sufficiently separate and able to appreciate the real aspects of their therapist, they can work increasingly collaboratively with him or her, i.e., they can establish a therapeutic alliance. To summarize, I belive that a sequence occurs in the successful therapy of primitive patients: 1) the establishment of stable self-object transferences that sustain them, 2) the increasing capacity to appreciate the therapist as a real and separate person, and 3) their gradual ability to ally themselves with their therapist in the service of accomplishing work.

Using these formulations, the therapist has as a major task the clarification of where the patient lies in this continuum, what causes the patient's fluctuations within it, and what responses by the therapist will solidify the patient's achievements as he or she advances along this developmental sequence. Thus the primitive patient's dissatisfaction that the therapist is not real to him or her may be viewed as the patient's failure to establish a sustaining self-object transference at that moment. The therapist's formulation and empathic understanding determines his or her responses at different times and is specifically related to a clarification or interpretation that addresses the appropriate point of the developmental sequence described earlier.

The therapist's comfort with himself or herself and the countertransference feelings that emerge with these primitive patients is an obvious but important factor in the ultimate outcome of the psychotherapy (13). This personal comfort can allow the therapist to be flexible and use his or her human qualities and warmth appropriately in the best interests of the patient. The combination of a theoretical model and an empathic flexibility can provide a framework in which the therapist can use his or her intellect and empathy for optimal psychotherapeutic work with this challenging group of patients and gradually increase our growing understanding of them.

A Psychoanalyst Reports at Mid-Career

BY JOHN E. GEDO, M.D.

The author states that the current pessimistic impression of the potential of psychoanalysis as a therapy is largely due to the inclusion of a disproportionate number of inexperienced analysts in reports on groups of practitioners. To correct this bias, he summarizes his own experience of two decades as a full-time psychoanalyst, describing his successful analyses as well as his unsuccessful attempts. He concludes that the satisfaction of commitment to a psychoanalytic career comes from the fact that it confirms the usefulness of the analytic method as a means to assist others to achieve personal growth and to illuminate human mental life.

REPORTS BASED on the work of groups of practitioners have created a misleadingly pessimistic impression of the potential of psychoanalysis as a therapy because such surveys have included a disproportionate number of inexperienced analysts. As a corrective for this source of bias, I propose to summarize my own experience as a clinician who has taken the unusual course of total immersion in psychoanalytic practice. The price one has to pay for such a choice is that of abandoning the hope of rendering service to significant numbers of people. Its rewards lie in the direction of perfecting oneself as a technician so that one can apply the psychoanalytic method in the area of its greatest utility, that of a unique research tool for the illumination of human mental life. The vast majority of psychoanalysts devote themselves primarily to patient care, spending most of their professional life performing treatments less time-consuming than the psychoanalytic procedure itself (1).

By contrast, over the past 20 years I have treated a total of 36 people (exclusive of those currently working with me). Among the patients who completed treatment, 28 terminated analysis on the basis of a consensus about the satisfactory outcome of the enterprise. The others were about evenly divided among those who interrupted treatment to resume later with me or elsewhere, therapeutic failures in spite of prolonged efforts, and patients who fled treatment against advice.

Received March 2, 1977; revised June 1, 1977, Sept. 26, 1977; accepted Jan. 10, 1978.

Dr. Gedo is on the Faculty of the Chicago Institute for Psychoanalysis. Address reprint requests to him at 400 East Randolph St., Chicago, Ill. 60601.

THE PATIENTS

My group of 36 patients, who were exactly divided between men and women, represented a relatively narrow segment of the professional and academic elite. All were white and were born in the United States. Nominally, more than half were Protestants, about one-third were Jewish, and there was a scattering of other faiths. By profession, one-third were in academic life, either as faculty or as graduate students, about a fourth were mental health professionals, and another fourth were evenly divided among journalism, the arts, business, and law. The women who were not employed were married to men of professional status. At the start of treatment, the patients were evenly distributed in the 22–46-year-old age range. Half of the patients had had some form of previous psychotherapy (some with me many years ago), and one-sixth more had been in analysis elsewhere.

Without exception, analysis was undertaken to alleviate the consequences of a complex and severe character disturbance. Most of these patients had decided on analysis only after a serious adaptive failure at work, in family life, or both, resulting in severe loss of self-esteem. The presenting clinical picture was often alarming, with depression, suicidal preoccupations, frantic perverse activities, panic, or psychosomatic decompensation. Whatever the symptoms, I adhered to an unvarying policy of accepting anyone with a serious commitment to seeking self-understanding if there was no clear risk of psychotic fragmentation or a likely need for hospitalization.

A fourth of the patients confronted the necessity for major character change following the dissolution of a marriage, and more than another fourth were currently experiencing severe marital strains. In fact, of the latter group, about half eventually dissolved their marriage. A third quartile consisted of people who had never married and who realized that their characteristic mode of relating to the opposite sex absolutely precluded having a satisfactory family life. Thus, fewer than one-fourth of my patients had reasonably gratifying intimate relationships. In the sphere of work, at least 1 in 4 had reached a dead end in their career and a like number were seriously dissatisfied with their professional progress. Overt adaptive difficulties account-

0002-953X/79/06/0646/04/$00.45 © 1979 American Psychiatric Association

ed for the decision to seek analysis on the part of all but 4 patients. These 4, most of whom were mental health professionals, sought help for subjective discomforts alone.

THE ANALYSIS

The analytic procedure was invariably carried out in the so-called classical manner (2, 3), one hopes in the spirit of humane common sense recommended by the best clinicians (4, 5). Actually, my schedule permits about 160 sessions per year if my patients and I meet 4 times a week (or 200 if we can manage 5 weekly appointments). With negligible exceptions, analyses that reach a successful conclusion require more than 600 sessions, sometimes as many as 1,000, spread over 3 to 7 years. People who interrupt treatment generally do so relatively early, usually after about a year of work. In only one instance did a patient decide to leave prematurely at a later stage. Conversely, in the cases that ended in failure, we did not reach that reluctant conclusion until the analytic process had been given a chance to unfold in the usual manner over a number of years.

Regardless of outcome, the decision actually to dispense with my services was left entirely to the patient. The analyst should only state an expert opinion about what remains to be accomplished and what the chances of reaching those goals might be. The duration of treatment did not turn out to be directly related to the severity of psychopathology; it seemed to be more closely tied to the specific issue of how rapidly I was able to develop a meaningful way of communicating with the analysand. That task is much more difficult with people who suffer from disturbances with a genesis in early childhood. Such developmental problems may impair the patient's language functions or even the capacity for rational thought. Cultural differences may also contribute to difficulties in communication.

The work of two decades was scarcely uniform in quality; significant changes are bound to occur over such a span. Increased experience may lead to greater skill, increased age brings older patients, and general progress in the field induces changes in one's approach. The factor of experience is easiest to pinpoint. By far the greatest proportion of my analytic failures occurred immediately after my graduation from a psychoanalytic institute, i.e., among the first patients I tried to treat without supervision. Perhaps the most meaningful change in my therapeutic philosophy has involved the gradual development of methods for dealing with the effects of earlier maturational vicissitudes on the typical intrapsychic conflicts discovered by Freud (6, pp. 153–168).

I cannot report on the results of my analytic efforts with complete confidence because of the lack of systematic follow-up study; perhaps only with incomplete cases can the ultimate outcome be gauged when the work is stopped. However, without my making any deliberate effort to learn about my former patients, relevant information has come to my attention about a substantial proportion of them. Such intelligence becomes available more or less automatically about mental health professionals who reside in the same community and about people with intimate friends or relatives in the analytic world. Occasionally, patients return for a consultation about some crisis in their life or that of a family member; others may write to communicate some piece of news, usually about a major accomplishment. As a result, I have learned something about the later outcome of most of the analyses that have successfully terminated. By contrast, I have seldom had news about patients who did not reach a successful analytic termination.

SATISFACTORY TERMINATIONS

Clearly, a satisfactory termination implies that the major defects in adaptive capacity which prompted the patients to come for assistance are no longer in evidence. Favorable results were particularly striking with regard to career problems. Patients whose analysis ended favorably have invariably done well in the sphere of work; often they have achieved impressive public success. In crude financial terms, analysis proved to be a sound investment for them. A number of patients, including some of the married women who had not been employed previously, launched new careers. Several women devoted themselves to rearing their children with enthusiasm and satisfaction. To my knowledge, only 1 of these patients has had subsequent problems with work; excessive ambition led this person to attempt more than he was qualified to achieve.

It is more difficult to assess outcome in the sphere of intimacy. An external criterion, such as the establishment of gratifying family life, cannot be used because it depends in part on circumstances beyond the control of the individual. Women older than 35 are less likely to marry than are younger women; among my patients, only one woman older than 35 married. Among men and among women under 35, about three-quarters entered permanent relationships after successful analysis, as far as I know. More importantly, all of the desperately strained, masochistic relationships that brought my successful patients into treatment had come to an end as a result of the work, either through separation or because of improvements, often facilitated by psychoanalytic treatment of the affected spouse.

In summary, the successfully terminated analyses were characterized, as a group, by extensive favorable adaptive changes in the capacity for productive work as well as in the capacity for gratifying personal intimacy. It may well be possible to obtain comparable results through other psychotherapeutic methods, but I have never been able to do so (7). Nor would I assume that the permanent disappearance of the more

threatening symptoms (perverse activities, hypochondriasis, psychosomatic crises, mood disorders) could have been accomplished only by psychoanalytic means. The therapeutic results should be regarded as specifically psychoanalytic only if they reflect actual maturation in those mental functions which subserve adaptation, i.e., if the results are sustained because the analysand achieved effective self-regulation in the areas of former limitations. Whether improved adaptation has really come about in these patients because of such learning or simply because they received continuous assistance through the relationship to the analyst is quite difficult to determine. This issue generally occupies the forefront in the termination phase of analysis; actual termination should be decided on only if there is reason to believe that improvements will be sustained without the continuing availability of the analyst.

The above description of successful terminations represents the estimate my patients and I made jointly in these cases. Obviously, this is a matter of judgment; only a formal follow-up study of long-term performance after termination can substantiate its validity. The analyst is naturally tempted to believe that no news from an ex-patient is good news, but this assumption is untested. I can claim only that the freedom of the great majority of my ex-patients to contact me when something newsworthy occurs in their lives (or about crisis situations, for that matter) argues for the probability that those who have not been heard from are not simply withholding unfavorable tidings.

The most significant negative information I have gathered about my successfully terminated patients highlights the limitations of my results. In two instances, the difficulties experienced by the ex-patient have required further analysis; a few others involved mental health professionals interested in psychoanalytic training who resumed analytic treatment in connection with their career requirements. One of the people who needed further assistance was the person who got into deep water by setting unrealistic vocational goals. Actually, this person had decided to resume analysis less than 6 months after termination, having returned to tell me with some bitterness about the intention to consult someone else. I have reported the specific dynamics of this disaster in another context (8). At the time of this announcement, the patient's discomfort was purely subjective; the adaptive breakdown that actually led to resumption of treatment occurred some years later.

The second case that required re-analysis was even more startling: the patient went from success to success in every sphere of life and eventually returned for help because of severe anxiety about this unprecedented state of affairs. The second analysis had to be performed by another analyst in another city, but I was informed that the issues which had arisen in the new situation were quite different from the ones this patient and I had dealt with. It would seem, then, that the analytic work had been incomplete in both instances, in spite of the fact that the procedure had been brought to a satisfactory termination in terms of the usual process criteria. An operation may look successful without truly benefiting the patient.

UNSUCCESSFUL ANALYSES

It is always easier to detect one's therapeutic limitations in retrospect. I believe mine have coincided, more or less, with those of the discipline as a whole in the past decade. I started the analyses I was unable to bring to a successful conclusion with some awareness of their potential difficulties. Most of these patients would have been turned away as unpromising by anyone interested in a perfect record as a therapeutic virtuoso. These individuals may not have been unanalyzable, but success could be expected only in unusually fortunate circumstances. For example, the one person who has interrupted treatment in recent years was a woman who had been seriously suicidal when we began. She went through a series of episodes of disorganization in the early stages of analysis, but the availability of assistance gradually calmed this turbulence. The patient was able to rationalize her flight from analysis on the ground that the resulting improvement in her life had more than satisfied her goals; in a literal sense, this was probably true. The therapeutic alliance was ruptured, however, by the emergence through free association of the patient's conviction that she was an evil heretic, unable to live by the rules of the religious sect that defined her entire adult existence. It was my unwillingness to concur in this delusional view that precipitated the crisis: I became the source of evil by telling her she was not a heretic—that the set of private religious convictions she lived by was just as worthy as the sect's official dogma. In trying to treat a prophetess through the psychoanalytic method, I was consciously trying to extend the range of its applicability.

The most obvious factor distinguishing the patients with whom I did not succeed, as a group, was the fact that the effort made was inadequate in the face of overwhelming difficulties. Poor prognostic signs were not always apparent early in the treatment. For example, one patient who eventually proved to be psychotic presented herself in a manner that misled me into seeing her as a hysterical personality. Months later, it emerged that she had been given that diagnosis by a previous consultant. Thoroughly familiar with the phenomenology implied by this term, she became the victim of her pathological suggestibility and unconsciously enacted the part of a model hysteric.

In terms of their ultimate diagnoses, the patients who continued in treatment for many years without appreciable progress had unresolved problems related to the most archaic developmental levels, i.e., they might fit the category of borderline personality organization. None of the successfully terminated analyses dealt with problems of that magnitude. Patients who

interrupted work with me even though they wanted to continue in psychoanalysis did not differ markedly in their personality organization from those I succeeded in analyzing. In these cases, it was impossible to establish a therapeutic alliance for complex reasons involving unfavorable reality circumstances relating to such specific character traits in these individuals as suspiciousness bordering on the paranoid (e.g., complicated third-party arrangements for payment and uncomfortably proximate professional and/or social contacts).

With regard to demographic criteria, a disproportionate number of patients in the unsuccessful group were in their 50s. The group also contained several individuals from cultural backgrounds relatively unfamiliar to me: the religious fanatic I have mentioned, people with a quasi-rural background, and a student radical descended from Italian peasants. I might add that the majority of these patients happened to be in some branch of academic psychology professionally. I wonder if it was more difficult for these institutional "rivals" to "submit" to psychoanalysis than it was for others. There is also the possibility that I have some unconscious prejudice toward them. At any rate, it is probably significant that 3 of these psychologists sought assistance for purely subjective reasons, i.e., without having sustained any demonstrable adaptive failure. I infer that the desire to seek analysis in the absence of any acute life crisis may indicate a sense of deep disturbance with unfavorable prognostic significance.

Failure of an analytic effort does not end the therapist's medical responsibility; on the contrary, such an outcome constitutes a potential emergency because patients are likely to react to it with a sense of catastrophe. There may be panic, depression, and paranoid accusations of maltreatment. It is imperative to deal with these contingencies in an appropriate therapeutic fashion. Treatment of these complications may require much time and effort. (In one case, my responsibility has actually turned out to be interminable.) If the therapist succeeds in demonstrating his or her continuing availability, the acute symptoms may subside; eventually, the therapeutic contact may then be tapered off. In one instance, the patient tried to disprove the unfavorable verdict by making strenuous conscious efforts to show improved adaptation. These attempts were somewhat beneficial, so that from an uninformed vantage point this "analysis" might have appeared to be successful. The patient finally left me with some bitterness because of my continuing insistence on the judgment that *analytic* treatment was not feasible.

The most difficult potential hazard after an analytic effort has failed is the emergence of a regressive state requiring hospitalization. This was the outcome with the "borderline" person whom I had misdiagnosed as having a hysterical personality; under the circumstances, I was obliged to transfer this patient into the care of others. Her subsequent treatment, however, was no more successful.

CONCLUSIONS

In describing my analytic experience over two decades, I have concentrated on observations about people and events. This is relatively easy, but it is also the less significant part of what needs to be said. The more meaningful side of these experiences is subjective, and this is almost impossible to describe adequately. Eighty years ago Sigmund Freud wrote that he found it difficult to convey the intellectual beauty of his work. Indeed, psychoanalysis continues to offer the kind of excitement, complexity, novelty, and rigor that characterize great art, scientific discovery, or other intellectual problem-solving on the highest levels. The evolution of our understanding of the complexities of psychic organization has entailed a corresponding increase in the therapeutic effectiveness of the analytic method. In principle, the analyst should not approach his or her clinical work with the personal need to be a healer; to require patients to improve is an illegitimate infringement on their autonomy. Nevertheless, much of the satisfaction of commitment to a psychoanalytic career comes from the continuous reconfirmation of the matchless usefulness of the analytic method as a means for personal growth.

Psychiatric Malpractice: The California Experience

BY PAUL FREDRIC SLAWSON, M.D.

The cost of psychiatric malpractice insurance has increased dramatically in recent years. To shed light on the extent to which this increase is justified the author polled 133 California psychiatrists who had indicated experience with some form of claims activity over the past 5 years. The 107 respondents reported 105 cases, of which 57 (54%) resulted in no more than a notification of a possible claim, 22 (21%) did not proceed beyond legal deposition, 20 (19%) were settled by dollar payment before trial, and 6 (6%) were left to the courts. The author recommends tort reform and refinement of reported claim and loss data to contain the cost of malpractice insurance.

IN THE PAST FEW YEARS an unprecedented number of patients have initiated lawsuits against doctors, asserting negligent practice of medicine. A "malpractice crisis" developed, and one result was that doctors were threatened with large increases in liability insurance premiums. This expense would be passed on to patients in the form of higher professional fees. The higher premiums reflected the insurance industry's response to an increasing number of liberal awards to patients whose complaints would have found modest, if any, satisfaction in the courts only a few years before. The largest number of suits were in the surgical specialties, particularly those associated with an immediate threat to life. In this area, awards based on estimates of the cost of long-term care, coupled with an allowance for inflation and compensation for pain and suffering, led to indemnity costs grossly beyond reasonable expectation. The insurance companies reacted by either sharply increasing their premiums or withdrawing from the market.

Until recently all of this had little impact on the practice of psychiatry. Professional liability premiums for psychiatrists have traditionally been low, reflecting an insurance industry belief that psychiatric practice involved infrequent occurrences of malpractice suits and a modest exposure to loss. However, in the last 3 years the cost of malpractice insurance for psychiatrists has increased substantially in almost all metropolitan areas. What was a minor office expense has become a major factor in the cost of practicing psychiatry. There is a need to justify this change.

The literature on psychiatric malpractice is scant. Studies have shown psychiatry to be a lower-risk form of medical practice but have provided more qualitative than quantitative insight into the nature of the problem. Bellamy (1) reviewed psychiatric malpractice cases that reached the level of the appellate court during a 15-year period and found that the number of cases increased in each of the successive 5-year periods studied. Rothblatt and Leroy (2) cited psychiatric malpractice figures for the years 1931 through 1971. Between 1931 and 1940 they noted only 3 cases. However, between 1941 and 1950 they found 7, and between 1951 and 1960 there were 9. During the last period of their study, 1961 to 1971, they found 25 cases. These data would suggest the probability of a significant change in claims experience during the period under study.

In an effort to gain a better understanding of a problem that was clearly going to be of concern to California psychiatrists, APA's Area Six conducted a survey of its membership to determine the frequency and extent of claims of malpractice. This was accomplished through a questionnaire sent to more than 3,100 psychiatrists in the state. The response rate was over 50%, and the initial results of this survey were reported in an earlier study (3).

A summary of the initial findings is provided below:

1. Of the 1,537 responding psychiatrists, just over 50% were involved in full-time private practice; 95% purchased malpractice insurance with average limits of liability in excess of $200,000–$600,000.
2. Almost all of the responding psychiatrists prescribed drugs, but less than 10% gave ECT.
3. Over 50% of the respondents had minimal hospital practice, and only 20% carried an average hospital caseload of more than 3 patients.
4. The responding psychiatrists made a total of 166 notifications of a claim or potential claim to their insurance company in the 5-year period from 1971 to 1976.
5. In a given year, about 2% of the insured psychiatrists had some form of claims activity.
6. Interpolation of claims frequencies of the doctors who reported more than 1 claim in the 5-year period revealed an estimated rate of claims or potential claim notification of 3 claims per 100 psychiatrists per year.

Presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8–12, 1978. Received Aug. 21, 1978; accepted Nov. 22, 1978.

Dr. Slawson is Associate Professor of Psychiatry, University of California, Los Angeles, Neuropsychiatric Institute, 760 Westwood Plaza, Los Angeles, Calif. 90024. He is also Chairman of APA's Area Six Insurance Committee.

0002-953X/79/06/0650/05/$00.50 © 1979 American Psychiatric Association

Although this information may give some idea of the frequency with which patient dissatisfaction occurs in general psychiatric practice, it does not provide insight into the nature of the problem or its impact on the quality of care, nor does it estimate the cost of this problem as manifested in subsequent litigation and indemnities paid.

It is my intent in this article to review the claims files obtained in the earlier study. For this purpose, 133 psychiatrists who indicated claims activity and who also supplied identification data sufficient to allow more detailed follow-up were asked to complete a supplementary form requesting additional information about the incident reported. This form included the age, sex, diagnosis, and site of treatment of the patient involved, the exact nature of the allegation, and the current status of the complaint (i.e., whether or not it had been resolved or was still pending). If the circumstance was resolved, information was requested with respect to the manner of settlement, the amount of indemnity paid, and whether the resolution was accomplished by settlement before trial, during trial, or in the form of a judgment subsequent to verdict. Inquiry was also made as to the psychiatrist's satisfaction with the manner in which the circumstance was handled by the insurance company and the defense attorney provided by the insurance company.

FINDINGS

Requests for more detailed information concerning malpractice experience were sent to 133 California psychiatrists who had indicated some form of claims activity during the years 1971 to 1976. This yielded 107 responses (80%) and a total of 105 cases or individual complaints suitable for review. The number of cases is smaller than the number of responses because some of the cases supplied by respondents were initiated and often settled before the 5-year period under study. Although a small number of respondents supplied more than 1 case, this was more than offset by the number of cases excluded for reason of a claim filed before 1971. The following data are derived from the 105 cases originating in the established time frame.

The Patients

Almost all malpractice actions are initiated by a patient or someone acting for a patient. Most of the patients involved in the 105 cases under study were middle-aged. Their age range was 12–74 years, and 60% of the patients were within the 25–55-year-old group. There were 4 patients under age 18 and 2 older than 65. Forty-seven of the patients were men, 55 were women, and the sex of 3 was not specified. Thirty-seven of the patients were diagnosed as having schizophrenia (including the borderline states), and 28 were considered primarily depressed. Manic-depressive disease, neuroses, character disorders, and a group of miscellaneous conditions, including organic brain syndrome, each made up less than 10% of the sample. Most of the patients were inpatients. Only 95 of the 105 patients could be classified. Of these, 73 were or had been hospitalized and 22 were exclusively outpatients.

The Incidents

Dissatisfaction with treatment is the major factor in most malpractice actions. In the 105 cases studied there were 114 allegations because a few cases contained more than 1 complaint. Twenty-nine of the cases involved suicide; this amounted to just over 25% of the cases reported. Mistake in diagnosis and/or improper treatment was claimed in 22 (19%). Drug reactions accounted for 19 claims (16%), and 15 cases (13%) involved the assertion of unlawful detention. There were 3 claims of improper sexual involvement and 2 alleged breaches of confidentiality. The range of complaints was broad; 24 cases (21%) could not be classified in a meaningful way. These included potential claims from such diverse activities as rendering first aid at an accident site to an assertion of libel.

The Outcome

Complaints of malpractice are resolved in different ways. Some are simply threats and become nothing more than a filed notice of a potential claim, but others involve a certain amount of legal and investigative work that may result in settlement or trial. Fifty-seven (54%) of the 105 reported cases have, to date, resulted in no more than a notification of a possible claim. Twenty-two cases (21%) have been subject to legal process up to and including deposition but have not proceeded beyond that point. A total of 20 cases (19%) were settled by dollar payment before trial. That leaves 6 cases (6%) for the courts. Of these, 3 have been tried and won by the defendant psychiatrists and 1 was abandoned in midtrial by a plaintiff acting as her own attorney. The remaining 2 cases have not yet come to trial.

Malpractice premiums reflect an effort on the part of the insurance company to anticipate losses. Threats of suit and legal-investigative procedures do not usually entail great expense. However, settlements and court judgments can be very costly. For this reason, the 26 cases that were settled or tried warrant closer study.

The patients involved in the 20 settlements ranged in age from 12 to 70 years. A majority were middle-aged. Thirteen of the patients were women and 7 were men. Seventy-five percent were or had been inpatients. Most were diagnosed as depressed or schizophrenic. The complaints settled were almost equally divided among suicide, claims of improper treatment, and adverse reactions to drugs. Only 2 patients had received ECT; in neither was ECT the issue. The average cost of settlement was $22,400, with a range of $120,000 to $500. Data on these 20 cases are summarized in table 1.

Five of the patients involved in the 6 cases that reached the court level were men and 1 was a woman.

TABLE 1
Summary of 20 Psychiatric Malpractice Actions Resolved by Settlement

Patient Number	Age	Sex	Hospital Status	Diagnosis	Allegation	Settlement (dollars)	Remarks
1	32	F	Inpatient	Depression	Failure to restrain	80,000	Patient jumped from window before transfer from general to neuropsychiatric hospital
2	42	F	Inpatient	Schizo-affective	Suicide in hospital	—	Settled by hospital; patient had received both medication and ECT
3	46	F	Inpatient	Schizophrenia, paranoid type	Improper filing of commitment paper	1,000	Alleged negligence of hospital clerical staff
4	30	F	Inpatient, outpatient	Depressive neurosis	Sexual advance while patient was under hypnosis	5,000	Lawsuit probably triggered by billing dispute
5	61	F	Outpatient	Organic brain syndrome	Improper release of clinical information	1,500	Letter containing clinical information picked up by union representative; patient did not sign release
6	23	M	Inpatient	Mental retardation	Failure to diagnose brain tumor	—	State hospital patient; tumor found 7 years after examination; settled by state
7	70	F	Inpatient	Acute manic episode	Improper restraint, fractured hip	1,000	Doctor held not at fault; insurance company paid nuisance settlement
8	23	F	Inpatient	Depressive neurosis	Wrongful death	25,000	Primary doctor on vacation; patient alleged she took tricyclic overdose; hospitalized; experienced convulsion, asphyxiation; patient died
9	34	M	Outpatient	Manic-depressive	Improper medication, lithium versus chlorpromazine	70,000	Case initially considered defensible; doctor destroyed records; insurance company settled
10	56	F	Inpatient	Psychotic depression	Failure to restrain, suicide	10,000	Private hospital, no seclusion room available; patient checked every 10 minutes; hanged herself with drapery cord
11	38	M	Outpatient	Phobic neurosis	Failure to diagnose	120,000	Driving phobia treated for 2½ years with improvement; progressive ataxia; neurologist diagnosed vitamin B12 deficiency without anemia; medical group settled
12	48	M	Inpatient	Manic-depressive	Improper medication	15,000	Patient alleged lithium caused neurological deficits
13	40	F	Inpatient, outpatient	Depression, schizophrenia	Improper use of medication	2,500	Patient alleged addiction and failure to warn of possible addiction; suit followed collection effort
14	65	F	Outpatient	Manic-depressive	Improper medication	2,990	Patient developed paralysis agitans; claimed symptoms were caused by amitriptyline
15	43	F	Inpatient, outpatient	Neurotic depression	Improper medication and treatment	60,000	Patient took chloral hydrate overdose, with subsequent aspiration, hypoxia, and brain damage
16	—	M	Outpatient	—	Failure to certify patient as air controller	2,000	Single visit, doctor refused request, attorneys settled
17	—	F	Outpatient	—	Bill dispute	2,500	Bill placed for collection, patient sued, attorneys settled
18	43	M	Inpatient	—	Failure to diagnose, failure to restrain	500	Suicide; patient eloped, jumped from bridge; doctor denied liability; insurance company settled
19	50	F	Inpatient	Schizophrenia, paranoid type	Improper treatment, faulty commitment	2,800	Patient alleged overmedication with sedatives, resulting in fall, and hospital failure to file proper form with district attorney
20	12	M	Inpatient	Neurotic depression	Failure to properly diagnose and refer for treatment	2,000	Youth referred to long-term treatment center after inpatient evaluation; while there he hanged himself

Their age range was 22–74 years. Five of the 6 were hospitalized, and 4 were depressed. Three of the 6 cases involved ECT. One patient objected to that form of treatment, 1 died as a result of cardiac arrest more than 2 hours after treatment, and the third committed suicide. The 3 other cases concerned an assault on a third party, a claim of harrassment by the psychiatrist, and an elopement followed by suicide. None of the court cases that have been tried was lost by defendant psychiatrists. Three doctors were absolved of all liability, 1 case was dropped during the trial, and 2 are pending (see table 2).

DISCUSSION

The survey from which these malpractice claims were derived provides no information concerning the

TABLE 2
Summary of 6 Psychiatric Malpractice Actions Moved to Trial

Patient Number	Age	Sex	Hospital Status	Diagnosis	Allegation	Judgment	Remarks
1	74	Male	Inpatient	Involutional depression	No informed consent, fraud, battery	For defendant	ECT case; patient claimed inadequate preparation for treatment, asserted alternative modes were not tried first
2	25	Male	Inpatient, outpatient	Schizophrenia, paranoid type	Failure to restrain	Pending trial	Patient in board and care facility; assaulted and killed passerby in street; suit by family of decedent
3	33	Female	Outpatient	Schizophrenia, paranoid type	Harrassment	Suit dropped in midtrial; for defendant	Patient claimed she was being followed by her doctor and his associates; patient acted as her own attorney
4	22	Male	Inpatient	Organic brain syndrome	Failure to restrain	Pending trial	Patient eloped from hospital, ran in front of a truck and was killed; hospital settled; doctor refused settlement
5	31	Male	Inpatient	Psychotic depression	Failure to restrain	For defendant	Patient drowned while on authorized hospital outing; patient had received ECT
6	62	Male	Inpatient	Involutional melancholia	Wrongful death	For defendant	ECT case, patient with known heart disease had cardiac arrest 2½ hours after ECT

claims experience of nonrespondents. This is a limitation of the technique. It is possible that doctors who have had more unfavorable malpractice experience are reluctant to talk about it. However, the reverse may be true. Many psychiatrists confronted with the threat of suit react with an indignation they are quick to share with both colleagues and their professional society. A personal follow-up of a random sample of members would be required to show that the respondents were not atypical.

Given this reservation, and in the absence of other data, these findings support a contention that psychiatric practice presents a low risk to professional liability insurers. The initial survey showed a rate of 3 claims or notifications of potential claim per 100 psychiatrists per year over a 5-year period. This part of the study shows that more than 54% of these claims were associated with no subsequent legal involvement and an additional 21% stopped short of any settlement or trial. This means that 75% of the claims involved no settlement, judgment, or court costs. The 20 cases that were settled cost the insurance companies a total of about $440,000 over a 5-year period, or about $88,000 per year. The 4 cases that went to trial resulted in no paid judgments.

If the total number of claims is reduced by those which are only threats of suit and legal-investigative procedures, leaving just the cases that were settled or involved the courts, a frequency of "significant" claims, i.e., those which could produce a substantial loss, can be calculated. For the respondent population this rate is .02 for the 5-year period, or .4 claims per 100 psychiatrists per year. This means that in a given year there would appear to be less than 1 chance in 200 for a psychiatrist to subject his or her insurance company to a significant loss.

The patients associated with these potentially more expensive claims had few characteristics that would set them apart from patients encountered in routine practice. They tended to be middle-aged and were diagnosed as depressed or psychotic. Suicide was the most frequent complaint. It was the issue in 6 of the 20 settlements and in 2 of the 6 court cases.

Problems with ECT were not a source of loss for the insurance companies. Although 3 of the 6 court cases involved patients who had received ECT, none resulted in judgments. Only 2 of the patients who received settlements had been treated with ECT, and ECT was not at issue in either case. Of the total of 105 cases of complaint, 9 patients had received ECT, but in only 3 was that form of treatment, as such, in question. In 2 of these cases the defendant psychiatrists were absolved by the courts, and the other case was dropped before any legal involvement.

Given the limitations of the survey, these data support an inference that the actual cost of insuring psychiatric practice in California (a populous state considered to have a high-risk legal climate) was modest during a recent 5-year period. Using a few reasonable assumptions, e.g., an average of $50,000 for legal and court cost per tried case and an average legal-investigative expense of $500 for each unlitigated claim, an estimated mean yearly loss per insured doctor can be calculated. For the psychiatrists who responded to this study, that loss amounted to $108 per year. That figure would cover all paid losses and the estimated claims expense but not the reserves set aside for the 2 untried cases, insurance administrative expense, or profit.

Most psychiatrists have been subject to a sharp increase in the cost of malpractice insurance. The extent to which such increases are justified is not known. Trent (4) reported loss data from APA's program, which show an increasing frequency of claims and larger amounts paid out as that loss experience matures. In the past few months there have been a number of large settlements and judgments against California psychiatrists. They will affect future premiums.

Efforts to respond to increased malpractice costs are already under way. The California legislature has enacted a law that provides a sliding scale of attorney contingent fees and requires periodic payment of larger awards and disclosure of collateral sources of payment in malpractice actions. The National Association of Insurance Commissioners (NAIC) has initiated a nationwide study of closed malpractice claims. Effective this year, that study will specifically identify psychiatric cases and report the nature of the maloccurrence as well as the cost of settlement. It will be some time before the data derived from this study can achieve sufficient credibility to influence the rate structure of psychiatric professional liability insurance. The actual dollar savings from these efforts will remain uncertain for at least a few years. All of the cost of malpractice insurance is eventually borne by the patient. Adequate tort reform and mandated refinement of reported claim and loss data offer the best chance for containment.

Characteristics and Disposition of Persons Found Not Guilty by Reason of Insanity in New York State, 1971–1976

BY RICHARD A. PASEWARK, PH.D., MARK L. PANTLE, M.A., AND HENRY J. STEADMAN, PH.D.

In order to develop an empirical profile of persons acquitted by reason of insanity from which policy could be developed, the authors studied all acquittals in New York State from 1971–1976. During this period 196 men and 29 women were found not guilty by reason of insanity. In contrast to adults admitted to state correctional facilities, the study group contained proportionately more persons who were white and older. The most frequent crimes for which subjects were tried were homicide, assault, and robbery. Most victims were acquaintances of the defendants. By 1976, 67 persons had been discharged after hospitalization ranging from 1 to 1,235 days. These defendants are still being followed after their return to the community.

PHILOSOPHICAL DISCOURSES on the insanity plea abound in the legal and psychiatric literature. Yet few empirical studies have dealt with the frequency with which the defense is employed, its success rate (1–3), and the characteristics and dispositions of the defendants involved (4–8). Despite the limited data available on the plea of not guilty by reason of insanity, legislators, prosecutors, and defense attorneys express chronic dissatisfaction with whatever statute happens to be contemporary law and exert periodic efforts to alter the law in some fashion. Considering the limited information available on this plea, such efforts must be based on subjective impressions of the manner in which the law operates and its consequences.

The present investigation concerns the characteristics and disposition of persons found not guilty by reason of insanity in New York State. The time frame used was from the effective date of a revised criminal law procedure (9) governing hospitalization of persons acquitted for criminal acts by reason of insanity, September 1, 1971, to June 30, 1976. This report deals with a comprehensive depiction of the defendants' backgrounds, offenses associated with acquittal by reason of insanity, and courses of hospitalization after acquittal. Future reports will focus on how these patients compare both with those acquitted during the last 6 years of the prior statute and with a group of felons convicted of similar offenses from 1971 to 1973.

The insanity defense in New York is basically governed by a modified American Law Institute rule with the irresistible impulse component of that rule deleted. According to statute, "A person is not criminally responsible for conduct if at the time of such conduct, as a result of mental disease or defect, he lacks substantial capacity to know or appreciate either: (a) The nature and consequences of such conduct; or (b) That such conduct was wrong" (10). After acquittal the defendant is automatically committed to an appropriate mental institution until such time as his or her mental state has been restored and he or she no longer poses a threat to self or others.

METHOD

Patient files of the New York State Department of Mental Hygiene were searched to identify all persons found not guilty by reason of insanity during the study period. The files of the Departments of Mental Hygiene, Correctional Services, and Criminal Justice Services were then abstracted to secure the basic data required for the subjects.

All of the inmates admitted to the state's adult correctional institutions during the study period were used as a comparison group. Originally, it had been intended that the comparison groups would comprise those populations of the state who, during the study period and as the result of alleged felonies, had been arrested, indicted, acquitted, and had indictments dismissed. Unfortunately, New York's criminal justice data are not organized to permit the drawing of such comparison populations. Despite some obvious limitations, it was therefore necessary to use adult inmates admitted to the state's correctional facilities as the comparison group. This inmate group included only those persons admitted from 1971 to 1975, since 1976 data were not available.

RESULTS

Frequency of Successful Pleas

During the nearly 5-year study period 225 individuals were adjudicated as not guilty by reason of insanity. In the 4-month period of 1971 there were 15 cases; in 1972, 25 cases; in 1973, 37 cases; in 1974, 55 cases; in 1975, 61 cases; and in the 6-month period of 1976, 32 cases. This number is considerably more than the 11 successful cases during the 1960s reported by Foster (11) and later by Stone (12). However, Foster's information was found to be incorrect, apparently due to faulty records that were corrected during our investigation. There were, in fact, 53 successful pleas in New York from March 1, 1965, to September 1, 1971.

Because in New York the insanity defense can be raised at any stage during a criminal trial, it was not possible to establish the frequency with which the plea was actually made and thus its success rate. Such a determination would necessitate an examination of the transcripts of all felony trials in the state, a task beyond the scope of our work.

Demographic Characteristics

Of the 225 cases in our study, 196 (87.1%) involved men and 29 (12.9%) women. In contrast, during the period September 1, 1971, to December 31, 1975, 96.3% of the admissions to the state adult correctional facilities were men and 3.7% women, suggesting a possible overrepresentation of women in our study population.

Blacks comprised 60 (26.7%) of the 225 cases; whites, 146 (64.9%); Puerto Ricans, 12 (5.3%); and persons from other ethnic backgrounds, 1 (0.4%). In 6 cases (2.7%), ethnicity was unknown. Of the comparison group, 56.5% were black; 26.9%, white; 16.4%, Puerto Rican; and 0.4%, other. These figures indicate an overrepresentation of whites and an underrepresentation of blacks and Puerto Ricans in our study.

Study subjects ranged in age from 16–77 years, with a mean of 36 years (average age for men was 36 years and for women, 33 years). Distribution of age did not differ significantly between the sexes. The average age of the prison group was 23 years (mean age of 27 years for men and 33 years for women). It should be kept in mind that the prison group represents only those persons admitted to adult correctional facilities in New York. Therefore the ages of the entire population imprisoned in New York, both juvenile and adult, would be substantially lower.

In general, our study group was much older than a general criminal population. Whereas criminal activity is typically regarded as "a young person's game" and individuals in the 15–30 age bracket represent a large proportion of all persons arrested and convicted, 62% of our study group were more than 30 years old and 28% were over age 40.

Hospitalization and Criminal Histories

Among the 196 male patients, 109 (56%) had had no psychiatric hospitalizations in a New York facility before the arrest date for the crime of concern. Eighty-seven had been hospitalized and accounted for a total of 227 separate hospitalizations; type of hospitalization was known in 80 cases. Fifty had prearrest hospitalizations that were exclusively civil. These 126 hospitalizations ranged from 19 subjects with 1 prior civil hospitalization to 1 individual with 14 such hospitalizations. Twelve individuals had been hospitalized under solely criminal code procedures for a total of 19 hospitalizations. The remaining 18 subjects has been hospitalized under both civil and criminal procedures. They totaled 44 civil and 38 criminal hospitalizations.

Of the 29 female subjects, 21 (72%) had no hospitalizations before their arrest. Seven had been hospitalized previously under civil statutes for a total of 15 hospitalizations. One had been hospitalized under civil statutes on 5 occasions and twice under criminal provisions.

One hundred twenty-five (56%) of the 225 study subjects had no prior arrest record. Those with prior records included 5 women (17% of the women) and 95 men (48% of the men). The entire male group, including those without previous arrests, averaged 2.4 arrests while the comparable mean for women was 0.4. For the 95 men with previous arrests, the mean number of arrests was 5.0 and ranged from 18 men with 1 arrest to 1 defendant with 21 arrests. The five women with prior arrests averaged 2.4 arrests.

The 100 persons previously arrested produced 492 arrests. Of these, 151 (31%) were against persons, including 9 for murder, 1 for negligent homicide, 69 for assault, 31 for robbery, 19 for sex offenses, and 22 others. Property offenses accounted for 152 previous arrests (31%). Various minor offenses such as disorderly conduct, criminal mischief, and promoting gambling resulted in 116 (23%) of the 492 total arrests. The remainder were drug related (N=40, or 8%) and weapon or burglar tool possession (N=33, or 7%).

Acquitted Offenses and Victims

Table 1 provides the distribution for the most serious crime for which the study subjects were tried. It is apparent that crimes of violence or potential violence against persons and, most specifically, some form of homicide represented the most frequent charge. Murder and manslaughter accounted for 133 (59%) of all criminal charges, while assault, rape, and robbery accounted for another 53 (24%) of the cases. It is striking that 90% of the women were charged with some type of homicide.

A comparison with the criminal charges against the prison admission group is relatively meaningless, since the study population was almost uniformly tried for the crime for which they were arrested, but crimes for

[1]A table listing the frequency of successful insanity pleas and the rates of the plea, by county, is available from Dr. Steadman on request.

TABLE 1
The Most Serious Crime for Which the Study Subjects Were Tried

Crime	Men (N=196) N	Men (N=196) %	Women (N=29) N	Women (N=29) %	Total (N=225) N	Total (N=225) %
Murder	96	49.0	24	82.7	120	53.3

Criminal sale of controlled substances	2	1.0	0	0.0	2	0.9

which the inmate group were tried and convicted typically represented the termination of a plea-bargaining process in which the initial charge was often drastically reduced.

The vast majority of cases for both sexes (83.5%) involved but a single victim; 6.7% involved 2 victims; 1.8%, 3 victims; 0.4%, 5 victims; in 7.6% of the cases there was no victim. Of the 163 cases in which hospital records noted whether there was a victim, 17 (10%) involved crimes having no victim, such as drug sales and arson involving an abandoned building. In 103 cases (63%) the victim was known to the patient before the crime. In this category, members of the patient's family constituted the largest target group. Twenty-one (13%) involved their children; 19 (12%), their parents; 16 (10%), their spouses; 5 (3%), other relatives; and 5 (3%), in-laws. By far, the most frequent victims of female subjects were their children (16, or 57%); most of these cases involved infanticide. Other victims known to the patients included well-known acquaintances (20, or 12%), boyfriends, girlfriends, and/or members of their family (4, or 2%), coworkers (3, or 2%), employers (2, or 1%), and casual acquaintances (8, or 5%). Thirty-two of the victims (19.6%) were strangers. Law enforcement officers represented an identifiable target group (11, or 7%). In all but one case the officer became a victim while pursuing his official duties. However, one case involved the slaying of an officer by a fellow patrolman.

County of Trial

The rate of successful pleas of not guilty by reason of insanity varied widely among counties. In 25 counties there were no successful pleas. A 3 × 2 tabulation of counties by 1970 populations of 1) 0–100,000 persons, 2) 100,000–500,000, or 3) over 500,000 and by rates of successful pleas of 1) .00–.20 or 2) above .20 per 10,000 population revealed no significant association between county population and rate of successful pleas. In this regard, for example, the highest rates were found in Albany (.63; population of 286,742), Steuben (.40; 99,546), Erie (.35; 1,113,491), and Genesee (.34; 58,722). In like manner, New York and Kings counties, both heavily populated areas of New York City, had rates of .25 and .05, respectively.[1] The vast difference between Albany County and the rest of New York should be noted in the context of the study of the increased frequency of acquittals due to insanity reported by Grunberg and colleagues (13). Albany County is so atypical that any inferences drawn from these data, particularly when they are as global as these investigators', should not be generalized to the rest of New York.

Unfortunately, the manner in which New York justice data are compiled does not permit the computation of rates of pleas of not guilty by reason of insanity based on arrest, indictment, acquittal, and dismissal data for each county. If, however, it can be assumed that the typical pattern of urban, suburban, and rural crime prevails in New York, a reasonable inference can be drawn that high rates of the plea do not necessarily occur in counties with high rates of arrest and indictment. Again, unfortunately, the mode of compilation of criminal justice data in New York does not permit a direct analysis in a manner comparable to that of Pasewark and Lanthorn (4), who found that the frequency of the insanity plea in Wyoming was unrelated to population magnitude or density but was inversely related to the rate of arrest and indictment within a county. Thus the more "brisk" the criminal justice business in a county, the less likely it was that the plea of not guilty by reason of insanity would be entered. In addition, Pasewark and Lanthorn found the plea to be more powerful than commonly supposed in that a larger proportion of defendants entering this plea had their indictments dismissed than did persons not entering the plea.

The variable rate of successful pleas among New York counties suggests the possibility that the appropriate legal statutes concerning the plea are not applied uniformly throughout the state. Although current data do not permit the determination of reasons for the differential rate observed, a number of considerations warranting investigation include differences in arrest and indictment rates; the presence of judges, prosecutors, and/or defense counselors from given counties who have a strong orientation toward a psychodynamic explanation of behavior; and the presence of articulate groups of psychiatrists who serve as expert witnesses in particular counties. In any event, the differential rate of successful pleas among counties should raise questions as to the wisdom of altering the statutory language governing the plea if the goal of such change is to ensure uniform and consistent application of the law.

Escape	1		39.00	39.00	0			
Absconding	1		94.00	94.00	0			

Hospitalization After Acquittal

Diagnoses associated with the 330.20 hospitalizations were available in all but 14 of the 225 cases (see table 2). It should be remembered that a substantial period of time typically intervened between the patient's arrest and his or her enforced hospitalization after acquittal. Hence it is quite probable that in some cases, overt symptoms present at the time of the criminal act had abated.

Of these 211 patients whose diagnosis was known, 155 (69%) were given the diagnosis of psychosis; 7 (3%), neurosis; 24 (10.7%), personality disorder; 5 (2%), mental retardation; and 9 (4%), nonpsychotic or having no disorder. Of the 155 persons categorized as psychotic, 128 were schizophrenic and 80 of these were of a paranoid type.

On June 30, 1976, the cut-off date for the research, 133 patients (59%) remained hospitalized; 67 (30%) had received complete discharges including 2 from conditional leave status, 3 from absent without leave status, and 3 from escape status. Two (0.9%) were in a family care program; 8 (3.5%) were on conditional release; and 1 (0.4%) was on leave over 60 days. Three

(1.3%) had escaped, and 2 (.9%) were absent without leave. Nine patients (4%) were deceased, a fairly high mortality rate for persons of this age group. Of these, 5 were known to have committed suicide.

Table 3 presents data on the length of hospitalization, by type of offense, for the 67 persons discharged by June 30, 1976. Hospitalization ranged from 1 to 1,235 days (both of these cases involved murder). Length of hospitalization did not seem specifically related to the severity of the offense, as would be expected since the criteria for discharge are recovery and lack of dangerousness rather than punishment for the criminal act.

Work is now under way to examine the arrest and rehospitalization rates of these persons acquitted by reason of insanity. Preliminary indications suggest that they are less often arrested than comparable groups of felons and felony defendants incompetent to stand trial. The next phase of the research will deal with crucial clinical and policy questions.

COMMENT

A number of the findings reported here serve to point out the need for empirical investigation into areas rampant with assumptions built on assumptions. Contrary to much popular opinion, defendants acquitted by reason of insanity are not all bizarre murderers. Only a slight majority (53%) of those acquitted in New York were murderers. More importantly, in all types of offenses the victims for the most part were acquaintances. The popular conception that acquittals due to insanity return persons to the street to kill more strangers is simply incorrect. Most of the prior violence was directed at family and friends, and it is probable that any subsequent violence would also be directed at these two groups.

Some of our findings were surprising. We had anticipated that the study group would include individuals with many pretrial psychiatric hospitalizations and only a few arrests. Instead, 56% of the men and 72% of the women had no prior psychiatric hospitalization; 95 men (44%) had at least 1 previous arrest, as did 5 women (17%). Further, these 100 individuals had a total of 492 arrests including 152 arrests for such property offenses as burglary (N=55), various forms of larceny (N=70), possession of stolen property (N=16), and 11 other such offenses. These prehospitalization arrests lead us to question the belief that all cases of insanity pleas in this particular population represent individuals who, as a result of or during a state of mental disorder, committed the crime of concern. Instead, a reasonable alternative thesis appears to be that this group represents at least two distinct subcategories. The first subgroup comprises those typically regarded as subjects for the insanity plea. These are persons whose act represents a criminal behavior associated directly with a mental disorder. The second subgroup might, instead, be representative of a larger criminal population that, like any other occupational group, contains a certain number of mentally ill individuals.

We also tend to believe that within the population using the insanity plea, there are other subgroups for which the classical classification of mental illness seems a misnomer. Among this group we include mothers who kill their children and an assorted category of persons whom we feel cannot be classified as mentally ill.

In our study population 14 of the 29 women killed their children. Although some in this group had obvious psychotic symptoms, from psychiatric reports there would seem to be many more whose basic condition was one of inadequacy as mothers and homemakers. Essentially, we should suspect that because of the mores of society concerning motherhood, there is a tendency for citizens, including psychiatrists and judges, to label hostility against children as a reflection of aberrant thought processes or behavior. Rather than accepting the fact that the child is that person with whom the mother probably has the most interpersonal contact and is therefore the most likely target for the mother's hostility, we instead view infanticide as abnormal and thus preserve our illusions of motherhood and the mother-child relationship.

Another subgroup of questionable insane status in our population appears to be "persons of respectability" for whom citizens can feel considerable empathy. This group included a professional who, hounded by racketeers for debts resulting from compulsive gambling losses, committed robbery and a bumbling, uncertain middle-socioeconomic-class youth who, rebuffed by female contemporaries, committed rape to determine whether he could, in fact, have an erection and ejaculation with a woman.

These latter classes of individuals, as well as the differential rate of successful insanity pleas among counties, cause us to question seriously whether the particular language of a given statute governing the insanity plea is the deciding factor in whether a person is so adjudicated. It seems more reasonable to us that more humane, less legalistic variables are involved and that, whatever the law might be, these factors will continue to operate.

Psychiatry and the Rhetoric of Models

BY BEN BURSTEN, M.D.

The term "medical model" has been increasingly used in discussions about the future course of psychiatry. The author examines various types of models and suggests that "medical model" is a rhetorical device which tends to obscure many important issues. He suggests that psychiatry avoid overrestricting its area of expertise.

DURING THE PAST three decades the profession of psychiatry has traveled so far and so wide that we have been repeatedly impelled to reflect on who we are and what we are or should be doing. This identity crisis is not unique to psychiatry, of course; identity crises seem to be a hallmark of the rapidly changing times in which we live.

Recent discussions about our "proper" identity have to a great extent centered around the issue of the medical model. Several writers (1-4) have urged that we embrace or return to the medical model. For example, Hackett (4) stated, "I predict that psychiatrists, should they continue winging their way through the heady atmosphere of nonmedical conceptual and therapeutic models, will soon find themselves an endangered species."

On the other hand, writers such as Spiegel (5) have proposed quite different models. In his 1975 Presidential Address, Spiegel suggested a model based on helping individuals in difficult human situations—a sort of decision-making model that he termed "managing risky choices." Brown (6) predicted that well into the next century, psychiatrists will be concerned not only with schizophrenic and depressed people but also with those who have "problems in living." Engel (7), while advocating a medical model, called for a "new medical model"—one that might or might not be embraced by those who seek psychiatry's "return" to the medical model.

I do not propose to resolve psychiatry's "identity crisis" in this paper. Rather, my chief purpose is to point out how the use of the term "medical model" may be so confusing and ambiguous that it interferes with rational discussion of the very real questions before our profession.

Received Dec. 12, 1977; accepted Feb. 10, 1978.

Dr. Bursten is Professor and Vice Chairman, Department of Psychiatry, University of Tennessee College of Medicine, 66 North Pauline, Suite 232, Memphis, Tenn. 38105.

MODELS

The term "model" is used in two related but different ways. In the epistemological sense, "model" describes a way of thinking, a device employed to guide us in our approach to a problem. It gives us procedural rules or simplifications that make complex situations more comprehensible to us. I shall use the term "conceptual model" when referring to the epistemological sense. Conceptual models are chosen, wittingly or unwittingly, by the thinker. There is no absolute epistemology that enables us to get at the truth. As Conant (8) noted, "A scientific theory is not even the first approximation to a map of the structure of the universe, or a part of it; it is *policy*—an economical and fruitful guide to action by scientific investigations" (italics added). The informal rules of admissibility of data, procedure, viewpoint, acceptance of previous viewpoints, and so forth (many of which have been called "models") are part of this policy. Engel (7) is quite correct in stating that "a model is nothing more than a belief system" whether that model be the hypothetico-deductive method, mind-body dualism, systems theory, or free will and human choice. This is not to say that conceptual models cannot be useful. Often they are very useful, but sometimes they may lead us into unproductive channels. Although conceptual models have been important in the development of the physical sciences, Stent (9) pointed out that the sciences which aim to understand man have depended even more heavily on epistemological support.

There are various types of conceptual models. According to Langer's use of the term (10), "A model is an ad hoc construction designed to make easier the understanding of complex abstract theoretical propositions through the use of more easily encompassable *pictorial or verbal analogies*" (italics added). An example would be Freud's physics model of psychic energy or his military model of competing forces in mental conflict. Despite the fact that many of Freud's models were reified by some psychoanalysts, Gedo and Goldberg (11) make it clear that they are models—analogies—used in order to make the complexities of mental functioning more comprehensible. Another example of this kind of conceptual model is the computer model of the brain. Using this model, we do not imply that the brain is a computer but rather that by this simplified analogy, we may get some insight into the way the brain works. These models are selective in what they reproduce, as Langer has pointed out, and we

0002-953X/79/06/0661/06/$00.55 © 1979 American Psychiatric Association

may have to employ several different models to grasp the situation we are trying to comprehend.

In another vein, there are several models for conceptualizing the etiology of mental illness. Lazare (12) has outlined four such models—the medical (I would prefer the word "biological"), the psychological (really the developmental), the behavioral, and the social. Instead of being analogies, the model aspects of these concepts of etiology are rules of procedure. For example, the biological model says, in essence, "Whenever you see mental illness, look to biology for the significant etiological data." This can lead circularly to the position advocated by Ludwig and Othmer (3), wherein the conceptual model of disease (illness) is rooted in biology. Here the rule of procedure becomes, "Absent a biological etiology, do not call the condition an illness."

Minuchin and associates (13) illustrated still a different dimension of conceptual models for thinking about causation. Instead of considering biological, psychological, or social models with their various implicit assumptions about what "really" causes the condition in question, these authors considered a model of causation itself. They rejected the exclusive use of the linear model in which the psychosomatic illness "is seen as contained within the individual" and is produced by antecedent events in the person's life. By embracing an "open systems model," they have seen pathology in the family system whose communicative feedback mechanisms maintain the status quo of illness. It is important to recognize that the authors did not deny the psychosomatic illness per se or its linear antecedent causes, such as physiological vulnerability or the effect of stress on the designated patient, but that they maintained that using only that model of causation results in incomplete and less fruitful understanding than using the systems model.

Another type of conceptual model dictating rules of procedure is the hard versus soft controversy. Hard approaches are sometimes referred to as "scientific," "empirical," and "quantifiable." They count as data only those items which are observable by others and are recordable. They discount introspective data such as meanings, feelings, and hopes, which are directly observed only by the patient. However, some of these introspective soft data can be converted to hard data if the introspections are written down in response to printed questions, such as in the Minnesota Multiphasic Personality Inventory. In this case, however, no inference need be made about how the patient feels; the data are those which he or she reports.

Finally, we might briefly consider the conceptual model of illness itself. This is perhaps less a model and more a matter of definition. Some (1, 3) include in the category of disease only that which has a biological dysfunction. While social influences may be important, they must interact with a biological weakness or produce a biological aberration in order for the event to be called "disease." As Ludwig and Othmer (3) stated, "When no sustained biological dysfunction can be demonstrated or presumed, no disease can be said to exist." An alternative view, as expressed by Fabrega (14), is that illness is a social convention indexed by certain negatively toned changes in behavior that society validates as sick. Friedson (15) has presented an extensive discussion of this point of view. A good example of the definition of illness as a social convention was the American Psychiatric Association's decision to no longer classify homosexuality as a psychiatric diagnosis. If, in the near future, we were to find that circulating maternal hormones so influence the organization of the developing brain of the fetus that a certain area of this brain maintains dominance over another area and thus enhances same-sex attraction, we would have the biological underpinning for homosexuality. However, would this clarify the question of homosexuality as a disease any more than cerebral dominant factors may influence left-handedness without defining disease status?

The criteria for illness that Parsons (16) proposed included that the deviance does not arise by choice and is essentially beyond the patient's control and that what is wrong can be understood rationally. While Parsons' definitions of illness and the sick role are seminal in sociological thought, they have been revised, developed, and expanded by others such as Friedson (15). What these writers seem to agree on is that "illness" as defined by our society is a natural process (even if bad luck gave one cholera, the cholera itself is a natural process) and the patient cannot choose to be rid of it. This lack of choice rests on a causal conceptual model that includes elements of both psychological determinism and free will. Other deviations, such as sin or crime, contain larger measures of choice.

Beyond these various conceptual models (and there are many others) we find a second use of the term "model." This is the usage in the social sense; it refers to the process of development or socialization and speaks to the question, "Whom does one pattern oneself after?" When referring to the social sense, I shall use the term "role model." While conceptual models refer to the way we think, role models refer to the way we act. Clearly, the way we act is in large part predicated on the way we think. And just as clearly, the way we think, the way we conceptualize a problem, is predicated on who we are in terms of social role, how we were trained, what depends on our actions, and how those whom we pattern ourselves after would analyze the situation. However, there are also differences. We may understand a situation in terms of a conceptual model but take no action because we feel that it lies outside our role. Or we may take on certain attributes of our role model, such as wearing a white coat, that have little direct bearing on the conceptual models we employ.

As with the conceptual model, the role model is also embraced, chosen. However, in addition, it is more dependent on validation by others. If one embraces the supernatural model of causation (a conceptual

model), one may or may not find others in agreement, but one is relatively free to continue to think with that model.[1] However, if one embraces the role model of a minister, one needs the validation of people who are willing to be ministered to.

THE MEDICAL MODEL

I do not believe that there is a clear-cut medical model to which we can either return or aspire. Like the "good old days of yesteryear," the medical model of old never really existed, except in the nostalgia of those who would like a simple and more comfortable life. Nonetheless, the term has increasingly been used in the rhetoric of the last 20 years, as if we knew what we meant when we used it. The medical model is a conglomerate of several of the types of models outlined above, but the various people who employ the term refer to different types of models. Therefore the term is ambiguous, and unless one listens carefully, one is apt to miss the hidden meanings (hidden models). As such, it can become a code word, like "the American way," with pejorative and loyalty connotations masquerading as philosophy. As we shall see, for a variety of reasons most psychiatrists probably want to be regarded as physicians and may be induced to embrace a medical model without clearly knowing what they are embracing.

Freud started as a physician, and his early hope was to root his psychology in biology—not in the analog model sense but in actuality. As his thinking evolved, he had to resort more and more to analogies. He employed the conceptual models of physics and sometimes military encounters in order to grasp what he was primarily interested in—mental functioning. While the psychoanalytic model of etiology has always left the door open for biology, it has been largely developmental, assuming what I term "the average expectable brain."[2] For those who exclude from their definition of disease those situations without biological dysfunction, psychoanalysis does not deal primarily with illness. If one takes the position that the medical model is to deal with illness, psychoanalysis may be defined outside the medical model. If, however, one subscribes to the definition of illness that rests on responsibility and the ability to choose to be well, it is clear that psychoanalysis, with its deterministic thrust, deals with illness. Even when he advocated lay analysis, Freud had in mind those aspects of the medical role model which treated patients. However, he discarded those aspects of the model which mandated that one needs a medical degree and other trappings of the medical role.

To people such as Erikson (17), however, the psychoanalytic reliance on the illness concept (defined not by biology but by the ability to choose) leads to role confusions for both doctor and patient. The latter part of the 1950s saw the emergence of "therapeutic" communities in hospitals, which began to place more responsibility on the patients themselves. There was a shift in many hospital programs from a causal concept based on a model of patient helplessness to one based on relative free will—a shift from illness to a deviancy more like crime. Along with this shift in conceptual models, as Hoffman and Singer (18) have noted, came calls for a shift in role models—away from the model of traditional physician authority and prestige.

It is of interest that these calls for moving away from the medical model were not aimed exclusively at those who held biological etiological concepts or who defined illness as biological dysfunction; they were also aimed at psychoanalysts who embraced a developmental psychological conceptual model and who defined illness as an inability to choose.

In the early 1960s Szasz (19) declared that mental illness is a myth. The models that entered into Szasz's thinking in the ensuing years are many and complex; they have been well analyzed by Moore (20). At the risk of oversimplifying, it can be said that Szasz combined the biological definition of illness with the causal conceptual model of free choice. On both of these grounds, then, he was able to exclude most behavioral deviations from the realm of illness. Building on this, he argued that the authority aspects of the medical role model are inappropriate and that the legal powers given to physicians as social validation of their roles as protectors of the public's health are misapplied when dealing with problems of behavior.

In the turbulent 1960s the radical psychiatrists turned vigorously against the medical model. The medical model they opposed was not so clearly based on the conceptual model of choice versus linear deterministic causality. Those who conceptualized causality at all worked with the dimension of etiology, and they found etiology to lie in the "sick society" rather than in biology or development. However, as Talbott (21) has pointed out, much of their attack was aimed against the psychiatrist's professional prestige, economic well-being, and authority and control—especially over the mental health workers. This, then, was in large measure an attack against the role model aspects of medicine.

The attack on the psychiatrist's preeminent position in the field of mental health has come from other quarters as well. The schools of psychotherapy that Karasu (22) termed "experiential" arose largely from the work of both psychiatrists and psychologists. These therapies share the concept of real and nonauthoritarian relationships. Their etiological model is essentially social, with alienation being a prime factor in preventing personal growth and realization of one's potential. They generally do not embrace an illness model and often dissociate themselves from the physi-

[1] I do not imply here that one's thought models are independent of a social matrix; I am talking about relative degrees of social validation.

[2] Bursten B: Brain, objective-relations, and character (unpublished paper).

cian role. Nonetheless, they come under the social and financial rubric of mental health.

Although behavioral therapies are practiced by medically trained and nonmedical therapists alike, they seem to have found more favor with those who advocate a return to the medical model. It is interesting and instructive to inquire why this is so, inasmuch as they are essentially psychotherapies. The model of etiology is not primarily biological, with the exception, perhaps, of the physiological responses treated with biofeedback. The behavioral model rests heavily on the concept of a learning etiology (12, 22)—usually the domain of the educator rather than the physician. It is probably because the behaviors that these practitioners are concerned with are considered "illness" by our society's definition. Ludwig and Othmer's list of bona fide psychiatric diseases (3) includes anxiety, phobic reactions, alcoholism, and obesity—all of which may be treated with behavioral techniques. Another reason that these techniques may be considered legitimately medical is that they rest on hard data that may be plotted on a graph and quantified. Further, the role of the behaviorist vis-à-vis his or her patient is generally more authoritarian than that of other psychotherapists—the benevolent authority and the prescriptive aspects of the medical role model are used.

While much of the rhetoric of the 1950s and 1960s urged abandonment of the medical model, even though different authors meant different things when using the term, the rhetoric of the mid-1970s has advocated a return. Why is this so? For one thing, the biological frontiers of our profession, so long impenetrable, have opened up with many exciting discoveries and theories. For another, we are living in a time when technology and hard data are increasingly valued, and despite the fact that we decry the impersonality in our society, we continue to revere numbers, be they Social Security numbers or correlation coefficients. For those who use the term "medical model" to refer to biological etiology, biological definition of illness, and the hard data model, current social trends give important validation.

Other trends in our society give impetus to embracing the medical model, although the definition of the term is more on a role than conceptual model basis. In the first place, we have become considerably threatened by therapists who do not have the M.D. degree. Secondly, and strongly related to the first point, the economic picture has changed. In the 1960s there was money for innovative social approaches, and the rhetoric of the times was tailored to the monetary sources. Now much of that money has dried up, and there is talk of a national health plan, which means physicians and medical models in order to tap this economic resource. Similarly, the guidelines used by many insurance companies make the medical role model useful. However, while this role model depends on the concept of illness, it does not necessarily depend on biology or hard data models. A third trend is the new look in health care distribution. There is a strong emphasis (with funds for training) on primary rather than specialized care. Psychiatry has not been defined as a primary care enterprise, but psychiatrists can play an important role as consultants working with the psychiatric aspects of primary care situations. Here the medical model is largely role-based. Whatever one's conceptual models (so long as they do not preclude the concept of illness), we are enjoined by some to take them into the medical clinics and on the general hospital wards. This medical model does not need to imply a biological definition of illness or a hard-data conceptual model. Psychiatrists may work comfortably with behavioral, developmental, and social conceptual models, with linear or systems models of causality, and any analog models we find convenient, so long as we do it in an indisputably medical setting.

There is another, more subtle social trend that impels the rhetoric of the medical model. After the turbulence and permissiveness of the 1960s, our society is retrenching. There are calls for "return" in many areas. Often this return implies greater structure and an increase in the weight of traditional authority. In the role model of medicine, the psychiatrist is cast as offering both a great tradition and firm benevolent authority.

Is there *a* medical model? I do not believe there is. There are many social reasons impelling us to identify ourselves as physicians. There are, of course, historical reasons as well. The term "medical model" becomes rhetoric when we embrace it for these social and historical reasons without there being a consensus on the definitions and models that underline it. In the process, we unwittingly and often uncritically embrace concepts that we might question were they made explicit. Even the role model of the physician is blurred. While we physicians deal with illness, we may disagree on how we define it. We also deal with more than illness. The traditional physician in the "good old days" was counselor, advisor, teacher, and sometimes the voice of moral authority. The heavy medical reliance on hard data has not been characteristic of physicians throughout history; indeed, talking with patients to gather data was probably more characteristic of the old medical role than the one to which we are supposedly to return. Few would dispute that the plastic surgeon is a physician; yet when he or she does cosmetic surgery, the medical model is extended beyond disease. The best pediatricians are as interested in promoting growth as in curing illness.

Siegler and Osmond (1) have described three types of medical models: the clinical, the public health, and the scientific (investigator) models. The roles (and hence role models) of these three vary and at times may be antagonistic to each other. All too often, in medical schools future clinicians are taught by scientific investigator role models, while public health is relegated to a peripheral position in the value system.

If it is impossible to define a single medical model on the basis of the conceptual models we employ and the role models we use as patterns, our difficulties are

compounded when we consider the role of other professions in health delivery in our country. Optometrists, dentists, podiatrists, and osteopaths all treat what is considered illness—indeed, even biological illness. Are we to say, then, that even the M.D. degree is not defined as a requisite for the medical model?

PROPOSALS

I propose, therefore, that we abandon the term "medical model" because it is ambiguous, and like other rhetorical devices, it represents a social and political thrust rather than a clear-cut conceptual or role model. As Langer (10) said, models should simplify and clarify; the term "medical model" obscures. Gedo and Goldberg (11) reminded us that we often must use several different models in order to understand complex situations; the call for a return to the medical model is a call for allegiance.

If we abandon the medical model rhetoric, we are still left with the problems and disagreements that underlie the discussion. I propose that we talk about each of the various true models that I have described above so that others may know more precisely what conceptual vantage points we are employing. We must identify the conceptual models we use and separate them from the role models we advocate. We seem to be suffering an identity crisis, and I am quite content to throw my lot in with medicine; I am a psychiatrically trained physician (role). This need not define my conceptual models. Indeed, if we adopt narrow loyalties to conceptual models, we will restrict our response repertoire. This can lead, for example, to the overprescription of antianxiety medications because we cannot comfortably shift to a social model of illness causation. Our repertoire may be dictated by our version of the medical role model: we may overprescribe antianxiety medications because "doctors prescribe medicine" and "I'm going to act the way doctors do."

More importantly, embracing this role will not insulate psychiatry from the current trends in health care. Nonphysicians do biological treatment, as I indicated above. Occupational therapists, art therapists, psychologists, and social workers all treat, and as more of the dollar goes for health care, they will increasingly embrace the illness concept.

There is little difficulty in distinguishing us from optometrists, dentists, podiatrists, and general osteopaths. Some would bolster our identity and attempt to secure our role by separating us from the occupational and art therapists, the psychologists, and the social workers. The distinguishing feature would be to define disease as biological dysfunction. But there is no safety here. Nurses are increasingly seeking independent practice and are being given the legal right to dispense medication. Doctors of Pharmacy are dispensing medication and sometimes are willing to do so only if they are the "primary therapists." Psychologists, too, are asking for training and authority to prescribe and are conducting research on the biology of behavior. Blurred roles are increasingly becoming a feature of health delivery, and our identity as physicians will not necessarily ensure that the care assignments and the money that accompanies such assignments will go to us.

Hackett (4) has advocated our return to the general hospital: "Unless we are at home in the medical setting we are homeless." However, we are not the only inhabitants of that home. Nurse clinical specialists are training to do liaison work. In addition, psychologists are currently asking for hospital privileges and are increasingly employed by departments of pediatrics and family practice to do the kind of work we psychiatrists feel we should do. This is partly due to economic reasons; at present they often do the work more cheaply. History has shown that this type of economy is only temporary; the price rises as professional status becomes more secure. However, the liaison "home" is not one that we psychiatrists can claim is ours.

What I propose, then, beyond dropping the medical model rhetoric, is that we do not limit our capacities by trying to retreat into the shelter of a specialty distinct from all challengers. It simply will not work, and we may become so precious and specialized that there will be little demand for what we do. If we lose our expertise in the broad aspects of the human condition, we will be pushed to the periphery of the health delivery system where we will become specialized adjuncts to those other professionals who set policies for hospitals, clinics, legal matters, etc. Instead, we should make a specialty of being able to weave all of the factors together in a holistic fashion. We should be able to deal with thought and behavior from a biological, developmental, behavioral, and social standpoint. In order to do this, we must retain the ability to embrace a variety of conceptual models and to move from one to the other as the situation seems to demand. It is an enormous and difficult task—a task well suited to our aspiration as a profession.

TOPICAL PAPERS: Biological Correlates of Some Psychiatric Disorders

Urinary MHPG Excretion in Minimal Brain Dysfunction and Its Modification by *d*-Amphetamine

BY WALID O. SHEKIM, M.D., HAROUTUNE DEKIRMENJIAN, PH.D., AND JAMES L. CHAPEL, M.D.

The authors studied the excretion of 3-methoxy-4-hydroxyphenlyglycol (MHPG) in 15 hyperactive boys and 13 controls. They further examined soft neurologic signs and clinical drug response to d*-amphetamine administration for two weeks in the hyperactive boys. MHPG excretion was significantly lower in the hyperactive boys than in the controls.* d*-Amphetamine decreased MHPG excretion significantly in the drug responders only. Pretreatment MHPG excretion did not predict clinical drug response. The responders had more soft neurologic signs than the nonresponders. Furthermore, soft neurologic signs were not related to pretreatment MHPG levels.*

IT IS GENERALLY recognized that the diagnostic category of minimal brain dysfunction (MBD), or hyperactive child syndrome, consists of heterogeneous groups (1, 2). Etiologies that are being considered include maturational lag (3), brain damage at birth or early infancy (4), a disorder of the arousal nervous system (5), and a disorder in the metabolism of one or all of the monoamines (1). It has been proposed that some of these disorders may result from familial-genetic predisposition (1, 2) and that the genetic component of the syndrome may be different in different groups (6).

The treatment of choice for MBD with hyperactivity has been *d*-amphetamine or methylphenidate (1, 2). In a majority of MBD children, these medications improve the symptoms of hyperactivity, impulsivity, and short attention span (1–4). The mechanism underlying the therapeutic action of *d*-amphetamine is unknown, but it is often called "paradoxical" in view of the calming effect this stimulant has on the behavior of hyperactive children.

Some 35% of hyperactive children fail to improve on *d*-amphetamine (7). Reasons for such "failures" may include misdiagnosis, inadequate plasma and tissue levels of the drug, individual differences in metabolism of the stimulants, and/or medication noncompliance. Another possibility is that the syndrome of MBD may consist of several biologically different entities which may or may not respond to stimulants. It has been suggested that the investigation of organic and genetic factors as they relate to treatment response in hyperactive children may clarify the identification of subgroups of MBD (2).

In an initial pilot study (8, 9), we presented data that suggested a specific relationship between central nervous system norepinephrine (NE) metabolism and MBD. We found that the basal level of 3-methoxy-4-hydroxyphenylglycol (MHPG), the main metabolite of CNS NE, was lower in 7 hyperactive boys than in 12 controls and that there was a further decrease when *d*-amphetamine, 0.5 mg/kg body weight, was given for 2 weeks. We also reported that those subjects who had a

Presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8–12, 1978; received April 6, 1978; revised Aug. 14, 1978; accepted Dec. 12, 1978.

Dr. Shekim is Assistant Professor and Clinical Director, Children and Youth Center, and Dr. Chapel is Professor and Chief, Section of Child Psychiatry, University of Missouri-Columbia School of Medicine, N119 Medical Center, Columbia, Mo. 65201. When this work was done, Dr. Dekirmenjian was with the Illinois State Psychiatric Institute; he is now Director, National Psychopharmacology Laboratory, Knoxville, Tenn.

positive history of childhood hyperactivity in the natural father had higher pretreatment urinary MHPG levels than controls, while those hyperactive children without such a history excreted lower levels than controls and the other MBD children.

The present report extends the preliminary investigations to a slightly larger sample and examines whether pretreatment urinary MHPG and its change secondary to *d*-amphetamine administration, in both drug responders and nonresponders, can differentiate subgroups of children with MBD. We also examined whether such subgroups will differ in the presence or absence of soft neurologic signs, considered by many as indicators of delayed maturation of the CNS or as signs of "organicity" in children with MBD (10, 11).

TABLE 1
Comparison of Hyperactive and Control Samples

Item	Hyperactive Children (N=15) Mean	SD	Control Children (N=13) Mean	SD
Age (months)	111	19	125	14
Weight (kg)	30	6	34	7
Height (cm)	134	10	138	10
Body surface (m^2)[a]	1.04	0.15	1.12	0.16
Creatinine (mg/24 hours)	605	167	653	122
Urine volume (ml/24 hours)	965	515	823	234

[a]Obtained from a nomogram modified by C.D. West from data of E. Boyd (12, p. 1713).

METHOD

Fifteen hyperactive boys aged 7–12 with full scale IQs above 80 on the Wechsler Intelligence Scale for Children and with no gross neurologic abnormalities were studied. Informed consent was obtained from all parents and children. The diagnosis of hyperkinetic reaction of childhood (*DSM-II*) was made by the Children Diagnostic Classification and the Children Diagnostic Scale of the NIMH Early Clinical Drug Evaluation Unit Assessment Battery for Pediatric Psychopharmacology. The children were admitted to an inpatient research ward after being free from all medications for at least 2 weeks. All children were given a complete psychological, educational, and behavioral evaluation. They were all given items 1–36 from the neurologic part of the Physical and Neurological Examination for Soft Signs (PANESS). Items 37 to 43 (tapping and the string test) were not given because they were considered cumbersome to administer. A score on the PANESS was obtained for each child based on the sum of the rating scores on items 1–36. There was no diet control in this study. While they were on the unit, the children attended the in-house school, which was located on the same floor, and were allowed to engage in routine everyday activities. Twenty-four-hour urine collections were obtained and completeness of urine collections was monitored by urinary creatinine levels. We discarded samples of low volume (<500 ml/24 hours) and suspiciously low creatinine (<8 mg/kg body weight) (12). Duration of stay was extended as needed if there was a suspicion of urine loss. A male external catheter with adhesive liner and latex material that eliminates leakage was used on all enuretic children (N=5). Sodium-metabisulfite, 0.5 g, was added to the urine samples as a preservative for MHPG, and the samples were refrigerated immediately after patients voided. Aliquots were frozen and later analyzed by electron-capture gas-liquid chromatography according to the method of Dekirmenjian and Maas (13). At the end of the first admission, the children were discharged and went back to school on *d*-amphetamine, 0.5 mg/kg, for a 2-week period, after which they were readmitted and urine was collected again as previously outlined. A minimum of two 24-hour urine collections was obtained from each hyperactive child during each admission.

Conners' Teacher Rating Scales were completed by the children's classroom teachers initially during the week before the first admission when the child was free from medications and then again during the second week before readmission while the child was out of the hospital but was taking amphetamine.

Healthy controls were children of faculty members and staff of the Children and Youth Center, matched for age and sex. Controls were given MHPG determinations but no medication or placebo. A total of four 24-hour urine collections was obtained from each control.

RESULTS

No significant differences were found between hyperactive boys and controls as to age, weight, height, body surface, urinary creatinine, or urine volume (table 1).

MHPG values are expressed in three ways: micrograms per 24 hours, micrograms per one square meter of body surface per 24 hours, and micrograms of metabolite per milligram of creatinine per 24 hours. However, when comparisons are made between subgroups of hyperactive children, the data are expressed in micrograms of MHPG per milligram of creatinine to adjust for the variability in the excretion of metabolites secondary to differences in age, weight, and body surface and to minimize the problem of incomplete urine sample collections if it were present (14, 15).

The group of children with MBD, as a whole, excreted lower levels of MHPG than controls (table 2). The administration of *d*-amphetamine, 0.5 mg/kg divided over two doses daily for two weeks, decreased the levels of MHPG in the hyperactive group (table 3).

Drug Responders Versus Nonresponders

Nine children improved clinically on the drug and 6 children did not as determined by pre- and post-treat-

[b]Posttreatment significantly different (p<.002, paired t test).
[c]Responders significantly different from nonresponders (p<.05, t test, two-tailed).

ment scores on Factor 1 (conduct problems) and Factor 4 (hyperactivity) of Conners' Teacher Rating Scale. The responders scored significantly higher on the PANESS and tended to be younger than the nonresponders; however, the age difference was not significant (table 3). The administration of *d*-amphetamine decreased urinary MHPG levels in the drug responders but did not change them in nonresponders (table 4). Thus, when drug response was defined as in table 3, pretreatment MHPG level did not significantly differentiate the responders and nonresponders, although it tended to be higher in the responders (table 4). On the other hand, posttreatment MHPG levels did significantly differentiate responders and nonresponders (table 4).

Pretreatment Urinary MHPG Levels

Seven of the hyperactive group excreted MHPG levels that were higher than the control mean; these were considered normal to high levels. Three of the 7 gave a history of hyperactivity and impulsivity in the biological father; 2 other children had been adopted. The 3 children with a history of hyperactivity in the father and one of the adopted children were enuretic. The other adopted child in the study gave a history of enuresis that stopped before his admission to the study. *d*-Amphetamine administration in this group significantly reduced MHPG levels in 4 children who were drug responders, but there was no meaningful change in MHPG levels in the 3 children who did not respond to the drug (table 5).

The remaining 8 children in the hyperactive group excreted pretreatment MHPG levels that were at least one standard deviation below the control mean and were therefore considered the low MHPG group. Only 1 child from this group was enuretic. *d*-Amphetamine administration significantly decreased MHPG levels in the 5 children who were drug responders, while it increased MHPG levels in the 3 who were nonresponders (table 5).

Soft Neurologic Signs

The drug responders differed significantly from the nonresponders in their PANESS scores (table 3). Furthermore, the drug responders significantly differed from the nonresponders in both the normal to high pretreatment MHPG and the low pretreatment MHPG groups (table 5).

DISCUSSION

In man, as well as in other species, MHPG is the main metabolite of central nervous system NE (16). It has been estimated that over 50% of urinary MHPG comes from the metabolism of NE in the CNS in man (17). Its excretion in the urine has been shown to vary in response to changes in sympathetic activity or stress (18, 19). The variability in excretion in response to changes in motor activity is not as clear: it was shown to vary with changes in motor activity in one report (20), but in another no such relationship could be found (19). It is generally agreed that high urinary MHPG levels could reflect a primary increase in activity of the presynaptic neurons or in norepinephrine output, as well as a resultant compensatory increase (21). It is also agreed that reduced urinary MHPG levels may be considered secondary to decreased rates of synthesis, turnover, or neuronal discharge of NE (21).

[b]Student's t test of independent means, two-tailed, comparison of responders and nonresponders.

Furthermore, destruction of NE terminals in animals has been shown to result in decreased urinary levels of MHPG (22).

Amphetamine has been shown to influence NE metabolism by increasing the release of NE from the presynaptic nerve terminal (23), by inhibiting the reuptake of NE by the presynaptic nerve terminal (24), and by inhibiting the intraneuronal enzyme monoamine oxidase (25). The first action tends to increase MHPG production, while the other two tend to decrease it (26).

In this study, reduction in urinary MHPG was correlated with clinical improvement in nine children and with no clinical improvement in three. However, the reduction in MHPG excretion was statistically significant in the drug responders only. In three other children who did not improve clinically, MHPG excretion increased.

The finding that hyperactive children with soft neurologic signs (high scores on the PANESS) respond better clinically to *d*-amphetamine is in keeping with findings of other clinicians (27, 28). Soft neurologic signs, which may indicate delayed maturation and/or minimal damage to the CNS (1, 10), have been used as a predictor of favorable clinical response to stimulant administration. In this study, all children with good clinical response to *d*-amphetamine had soft neurologic signs (i.e., high scores on the PANESS), while none of the children who lacked soft neurologic signs (i.e., low scores on the PANESS) responded favorably to the drug. There seems to be a developmental trend in PANESS scores (29), and the higher PANESS scores in the drug responders may have been a result of such a trend, since the responders were younger. Thus, it might follow that whatever abnormality is causing the soft signs also renders the CNS NE system more responsive to stimulant medication.

COMMENT

Our data so far suggest that there is a relationship between minimal brain dysfunction and CNS NE metabolism and that there may be a relationship between

clinical drug response to *d*-amphetamine and change in NE metabolism.

We also found that pretreatment urinary MHPG levels do not differentiate responders and nonresponders to *d*-amphetamine in the fixed dose of 0.5 mg/kg divided over two doses daily for two weeks when drug response is determined by a decrease (at least 2 SDs) from the population mean on the hyperactivity factor of the Conners' scale. There is evidence that drug responders may come from the group with normal to high MHPG as well as from the group with low MHPG. Moreover, the presence of soft neurologic signs in hyperactive children improves their chances to respond favorably to *d*-amphetamine.

Finally, there does not seem to be a relationship between soft signs and pretreatment urinary MHPG levels. Children with soft signs fall into the normal to high MHPG group and the low MHPG group.

Amino Acids in Bipolar Affective Disorders: Increased Glycine Levels in Erythrocytes

BY SEYMOUR ROSENBLATT, M.D., GERALD E. GAULL, M.D., JACOB D. CHANLEY, PH.D., JESSE S. ROSENTHAL, M.D., HARRY SMITH, PH.D., AND LASZLO SARKOZI, PH.D.

The authors measured the concentrations of 20 amino acids in the erythrocytes and plasma of 13 female bipolar patients and 10 female normal controls. The concentration of glycine in the erythrocyte was significantly elevated in the patient group. No differences were present in the plasma. Preliminary findings indicate that the high glycine levels were present in patients who were depressed, manic, or in remission and were unaffected by electroshock therapy.

A NUMBER OF abnormalities have been reported in the erythrocytes of patients with affective illnesses. The activity of erythrocyte catechol *O*-methyltransferase (COMT), an important enzyme in biogenic amine metabolism, has been reported by some, but not all, investigators to be different in patients with primary affective disorders than in normal control groups (1). The biochemical properties of the erythrocyte enzyme indicate that it is probably identical to brain COMT (2). The erythrocyte also contains an active cation transport system similar to that of the neuron (3). In patients with affective illness there is a decrease in the activities of the erythrocyte Na^+ pump and ouabain-sensitive Na^+,K^+-ATPase (4). Both are stimulated with the administration of lithium, and the increase in activity may be related to the improvement of depressive states and the prophylactic efficacy of lithium maintenance therapy (5).

The erythrocyte, therefore, is a useful cellular model for investigating some of the physiological characteristics of the affective disorders. Because amino acid transport also is under the control of an active, energy-dependent carrier system (6), the concentrations of amino acids in the erythrocytes and plasma of manic-depressive patients were examined.

METHOD

The patients consisted of 13 women, 33–72 years old, who had affective illnesses of 10 to 20 years in duration. Ten were bipolar manic-depressives, and 3 were considered to have schizo-affective illness because of their psychopathology during acute episodes. However, because there were no residual symptoms, decrement in functioning, or personality deterioration after remission from multiple acute phases of illness, a diagnosis of manic-depression could be equally valid. The control group consisted of 10 female hospital personnel, aged 24–58 years, without personal or family history of an affective illness. They were in good health and not on any medication. Neither group was taking oral contraceptives. Six patients and 8 controls were premenopausal, and 7 patients and 2 controls were in menopause.

Of the 10 bipolar patients 3 were in remission and receiving 600 mg/day of lithium carbonate. These patients had not had an affective illness for at least 1 year, were in good health, and were not hospitalized for this study. Lithium carbonate was stopped for 7 days in these patients before blood was taken for amino acid analysis. Of the 10 hospitalized patients, 8 were depressed. Prior to admission they were under treatment with inadequate dosages of tricyclic antidepressants and had not been on maintenance lithium carbonate therapy. Two of the hospitalized patients were in the manic phase of their illness. At the time of hospitalization, all medication was discontinued for the depressed patients but was not interrupted for the 2 manic patients, 1 of whom continued to receive lithium carbonate (1200 mg/day) and the other haloperidol (10 mg/day). All 13 patients underwent routine physical examinations and complete blood and laboratory studies. Except for 1 patient, a known diabetic, all of the findings were within normal limits. The diabetic patient had an elevated fasting blood glucose of 180 mg/100 cc but was not excreting ketone bodies. This

patient was placed on a 1,200-calorie diet and given additional insulin, which brought the diabetes under control. Dietary control was maintained in the other patients by the use of liquid nutritional supplement (Sustecal). The patients drank 12 ounces of the supplement whenever they ate less than 50% of any meal. The daily caloric intake of these patients was never less than 2,000 calories. The patients were on the dietary regimen in addition to being drug-free for at least 5 days before blood was drawn for amino acid analysis after an overnight fast. The control subjects were instructed to adhere to their usual diets. It was ascertained that they were on conventional balanced diets; none was on a weight reduction diet.

Blood (15 cc) was drawn into heparinized vacutainer tubes and immediately centrifuged at 4,000 *g* for 25 minutes at room temperature. After the plasma was aspirated, the buffy coat of white blood cells and platelets was carefully removed with a Pasteur pipette. An additional 2 ml of the adjacent packed erythrocytes was also removed and discarded. The remaining erythrocytes were diluted with 2 volumes of distilled water and vigorously stirred. The lysed cells and plasma were stored at −70°C until analyzed. Amino acid concentrations in the plasma and erythrocytes were determined with an automated Technicon amino acid autoanalyzer (7).

FIGURE 1
Concentrations of Erythrocyte Glycine in Patients and Controls[a]

[a]Prediction equations: patient, glycine=75.79−0.3932 × Age; control, glycine=53.09−0.3932 × Age.
[b]Nonhospitalized patients.

RESULTS

The concentration of erythrocyte glycine was significantly higher in the patient group than in the control groups (56.3 μmol/100 ml±2.5 versus 37.4 μmol/100 ml±1.8) ($p<.001$). There were no differences in plasma glycine. Except for a modest increase in serine ($p<.02$) in the patients' erythrocytes (but not in their plasma) no further differences were observed. The other amino acids measured were taurine, aspartate, threonine, asparagine, glutamate, glutamine, proline, alanine, valine, leucine, isoleucine, tyrosine, phenylalanine, ornithine, lysine, histidine, methionine, and glutathione.

Erythrocyte glycine concentrations, ages, and menstrual status are shown in figure 1. No overlap was present between the patient and control values. Glycine levels of the patients were significantly higher than those of the controls as shown by parallel prediction equations. Glycine levels decreased with age. The slope of glycine versus age was −0.2456 for the controls and −0.4530 for the patients, and a t test for difference between the two slopes was not significant ($t=.92$, $p<.30$). The pooled estimate of the slope was −0.3932. The mean age was 39.8 years for controls and 49.6 years for patients.

The differences between the erythrocyte glycine levels of the premenopausal patients and controls could conceivably have been due to the time of sampling, with respect to the stage of the menstrual cycle. These data were not obtained at the time of the study. Although there are no reports as to changes in erythrocyte amino acids with the menstrual cycle, variations in plasma amino acids do occur. In normal women there is a decrease in serine ($p<.02$), glutamate ($p<.02$), and ornithine ($p<.01$) in the second half of the cycle (8). We observed no significant differences in these plasma amino acids between the patient and control groups, which would suggest that the time of sampling of these two groups was not skewed toward different stages of the menstrual cycle.

Three patients (2 manic and 1 depressed) underwent a course of electroshock therapy during which time all psychotropic drugs were stopped. Additional amino acid studies were done throughout this period and again about 3 weeks following the last treatment. These 3 patients were in clinical remission at this point, had been home for 2 weeks, and were not taking psychotropic drugs. No significant changes occurred in the levels of glycine or other amino acids in the erythrocytes or plasma. Although these conditions would appear to rule out the role of drugs in contributing to the elevated glycine levels, residual drug effects cannot be completely eliminated at this time. Long-term malnutritional effects must also be considered among those variables that might have contributed to the high glycine values. In addition, a number of control subjects will be placed on the same dietary regimen as the patient group in future studies.

DISCUSSION

The increase in erythrocyte glycine without significant changes in the other amino acids makes it unlikely that the differences found are due to an alteration in cellular transport. Glycine shares a carrier-mediated transport system with proline and alanine (9), and the concentrations of these amino acids were not affected. The elevation of glycine could not be attributed to a diminished synthesis or increased degradation of gluthathione in the erythrocytes since the tripeptide concentration was not decreased in the patient group.

Although glycine undergoes numerous metabolic transformations, its primary metabolic pathway is via the glycine cleavage system (10). It is therefore reasonable to speculate that the observed increase in glycine levels may be due to an impairment of this system, which degrades glycine to CO_2+NH_3 with concomitant formation of *N*-5,10-methylenetetrahydrofolate from tetrahydrofolate. Methylenetetrahydrofolate reductase and serine hydroxymethyltransferase but not the glycine cleavage system have been measured in the erythrocyte (11). Although the glycine cleavage system is present in mitochondria that are absent in the erythrocyte, the exclusion of this system from the erythrocyte has not been demonstrated. Glycine, however, may be increased in other tissues and transported to and retained in the erythrocyte. It has been shown that following parenteral infusions of amino acids, tissue levels can be elevated without concomitant changes in plasma levels (12).

It is not known whether the increase in glycine in the erythrocytes is also present in the brain where the glycine cleavage system is the main degradative pathway (13). It is conceivable that a moderate elevation in the central nervous system may affect amino acid and protein metabolism. Glycine is also an inhibitory neurotransmitter in the lower brain and spinal cord and an increase in cellular availability might be expected to affect this action (13).

The consequences of a defect in the glycine cleavage system is seen in the genetic disease, nonketotic hyperglycinemia, which is due to a severe inborn deficiency of this system. The disease results in marked neurological damage, convulsions, and death (14); however, there is a recent report of several affected infants in whom minimal or no neurological symptoms were found (15). Apparently a mild form of this disease can exist that is symptomless and compatible with life.

Although no apparent differences were noted between patients in mania, depression, and remission, the number in each group was too small for statistical analysis. A larger series of patients should be studied longitudinally with multiple sampling through various stages of the illness and remission in order to determine whether the glycine levels remain unchanged. If this situation is replicated, one could conclude that an elevated erythrocyte glycine level represents a metabolic defect (underlying amino acid disorder) that predisposes to the development of bipolar illness (in women) or is a genetic marker for those at risk. To our knowledge, this is the first observation of an abnormality in the affective illnesses that involves an amino acid not directly related to biogenic amine metabolism. This preliminary finding requires replication with a larger number of patients before it can be considered a specific and distinguishing characteristic of this patient subgroup.

Beta-Adrenergic Receptor Function in Affective Illness

BY GHANSHYAM N. PANDEY, PH.D., MAURICE W. DYSKEN, M.D., DAVID L. GARVER, M.D., AND JOHN M. DAVIS, M.D.

In a study of β-adrenergic receptor sensitivity, the authors determined the response of cyclic AMP synthesis to in vitro addition of norepinephrine (NE) and isoproterenol (IP) in leukocytes of patients with affective illness and schizophrenia and of normal controls. IP-stimulated increase in ^{3}H-cyclic AMP synthesis in depressed patients was significantly lower than in normal subjects and schizophrenic patients. These results suggest that β-adrenergic receptor sensitivity is reduced in depressive illness.

IT HAS BEEN proposed that affective illness and schizophrenia may be associated with a dysfunction of biogenic amines. A functional deficiency of norepinephrine (NE) or serotonin (5-HT) may be involved in certain types of depressive illness, while an excess of these amines may be present in mania. Schizophrenia, on the other hand, has been related to hyperactivity of the dopaminergic (DA) system. Abnormality of amine function may be caused by alterations in amine levels as a result of changes in their biosynthesis, release, reuptake, or metabolism, or it may be due to an imbalance in the transmitter systems. It is also possible that amine dysfunction results from altered sensitivity of the amine receptors. This has recently been reemphasized by Aschroft and associates (1), who suggested that tests of neuronal sensitivity in man should be developed to further evaluate this possibility.

For the past several years we have investigated the possibility that an abnormality of catecholamine receptors is associated with schizophrenia and depression. Using a neuroendocrine strategy, we recently demonstrated that hypersensitive DA receptors may be associated with a subgroup of patients diagnosed as having acute schizophrenia (2). Another indirect method for the study of biogenic amine receptor function in psychiatric illness involves the use of the cyclic-nucleotide system.

Cyclic AMP, which is formed by the catalytic action of the enzyme adenylate cyclase on adenosinetriphosphate (ATP), mediates the cellular effects of several hormones and neurotransmitters in both peripheral and brain tissues (3, 4), and neurotransmitters such as NE have been shown to increase the concentration of cyclic AMP in the brain (5, 6). Cyclic AMP, which has been implicated in synaptic transmission (7), has been found to be related and closely coupled to adrenergic receptors (7, 8). It is thus possible to study adrenergic function by studying adenylate cyclase responses to NE produced by human peripheral tissues.

In order to investigate adrenergic receptor sensitivity in affective illness further, we have studied leukocyte adenylate cyclase and its responsiveness to NE and isoproterenol (IP). It has been reported that alterations in cyclic AMP synthesis produced by NE and IP in human leukocytes are primarily β-adrenergic receptor responses (9). The presence of adrenergic receptors in human leukocytes was demonstrated by Williams and associates (10) in direct binding studies with ^{3}H-dihydroalprenolol (DHA).

Because human leukocytes are easily available, they provide a useful peripheral model for the study of β-adrenergic receptor sensitivity in a variety of pathologic conditions. Leukocyte adenylate cyclase and its responsiveness to NE and IP have been studied in subjects with bronchial asthma (11-13); however, to our knowledge, studies of leukocyte adrenergic receptor sensitivity have not been reported in patients with psychiatric disorders.

METHOD

Subjects were patients hospitalized on the research ward of the Illinois State Psychiatric Institute. Diagnoses, according to the Research Diagnostic Criteria of Spitzer and associates (14), were as follows: major unipolar depression, N=21; bipolar mania, N=9; and schizophrenia, N=29. Bipolar patients were all manic at the time of admission. Normal controls (N=26) were nonhospitalized volunteers who were free of any known major medical or psychiatric disorders. The subjects gave written informed consent to participate in the study.

Presented as a New Research paper at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8-12, 1978; received July 10, 1978; revised Nov. 27, 1978; accepted Dec. 15, 1978.

Dr. Pandey is Director, Biological Research Laboratories, Illinois State Psychiatric Institute, 1601 West Taylor St., Chicago, Ill. 60612, where Dr. Dysken is Chief, Clinical Research Ward, Dr. Davis is Director of Research, and Dr. Garver was Associate Director of Research when this work was done. Dr. Garver is now Associate Professor, Department of Psychiatry, University of Cincinnati Medical School, Cincinnati, Ohio. Dr. Pandey is also Research Assistant Professor and Dr. Davis is Professor, Department of Psychiatry, Pritzker School of Medicine, University of Chicago.

The authors thank Ms. L. Kujovick for technical assistance.

TABLE 1
Percent Conversion of Total ^{3}H-Nucleotides to ^{3}H-Cyclic AMP In Intact Human Leukocytes[a]

Diagnostic Group	Basal[b]			PGE_1 (10^{-5} M)			NE (10^{-4} M)[c]			IP (10^{-4} M)[d]		
	N	Mean	SD	N	Mean	SD	N	Mean	SD	N	Mean	SD
Normal subjects	26	0.25	0.02	26	1.77	0.18	26	0.42	0.04	21	0.68	0.06
Unipolar depressed patients	21	0.29	0.03	21	1.34	0.12	19	0.20	0.03	17	0.31	0.05
Bipolar patients with mania	9	0.24	0.02	9	1.54	0.26	9	0.28	0.04	8	0.40	0.05
Schizophrenic patients	30	0.27	0.02	29	1.48	0.21	30	0.26	0.05	26	0.51	0.08

[a]The percent conversions in the presence of NE, IP, or PGE_1 are those observed with the addition of these drugs over the basal activity and have been referred to as stimulated activity.
[b]Percent conversion when no test drugs were added to the incubation mixture.
[c]NE stimulation differed significantly between the groups, $F(3, 80)=4.14$, $p<.009$, and between normal subjects and patients, $F(1, 80)=10.08$, $p<.002$.
[d]IP-stimulated activity differed significantly between groups, $F(3, 68)=4.59$, $p<.006$; for normal subjects versus patients, $F(1, 68)=10.08$, $p<.002$; for normal subjects versus depressed patients, $F(1, 68)=12.61$, $p<.001$; and for schizophrenics versus depressed patients, $F(1, 68)=4.04$, $p<.05$).

Leukocyte adenylate cyclase studies of patients were performed at the end of a three-week drug-free period. Intact leukocytes were isolated according to the method described by Bourne and associates (15, 16). For the determination of adenylate cyclase, the pulse-labeling technique previously described by Kuo and DeRenzo (17) and by Shimizu and associates (18) was used; the procedure is similar to that described by Wang and associates (19). Leukocyte pellets were suspended in Tris-balanced buffer (pH 7.4) and incubated with ^{3}H-adenine (50 μCi) for 1 hour at 37°C. The suspension was then centrifuged at 2,500 g for 15 minutes, and the pellet was washed twice with Tris buffer and suspended in the buffer (1.5 to 2.5 ml). Final incubation of aliquots of the suspension was done at 37°C for 10 minutes in Tris-balanced buffer containing 10 mM $MgCl_2$, 1mM theophylline, and in the presence or absence of NE, isoproterenol (IP), or prostaglandin E_1 (PGE_1) in a total volume of 0.5 ml. The reaction was terminated by addition of a solution of cyclic AMP. The ^{3}H-cyclic AMP formed was isolated and quantitated according to the method of Krishna and associates (20) as described by Wang and associates (19). The results are expressed as percent conversion of total incorporated ^{3}H-nucleotides to ^{3}H-cyclic AMP.

RESULTS

Addition of dextro-levo IP, the β-adrenergic agonist, in vitro causes a dose-dependent increase in the production of ^{3}H-cyclic AMP. Similarly, NE and PGE_1 cause a dose-dependent increase in ^{3}H-cyclic AMP synthesis in leukocytes. The increase produced by IP is blocked by the addition of propranolol, a β-adrenergic antagonist, but not by phentolamine, an α-adrenergic antagonist. Because similar results are observed with NE, this suggests that the stimulation of ^{3}H-cyclic AMP synthesis in human leukocytes produced by NE and IP is a β-adrenergic receptor response. Stimulation of ^{3}H-cyclic AMP produced by the addition in vitro of PGE_1, however, is not blocked by propranolol.

Adenylate cyclase activity and the stimulation produced by addition in vitro of PGE_1 (10^{-5} M), IP (10^{-4} M), or NE (10^{-4} M) were determined in the 26 controls and 59 patients. The mean basal activity observed in the patient population was not significantly different from that in the control group (table 1). In vitro addition of PGE_1 (10^{-5} M) produced an approximately 6-fold increase in net ^{3}H-cyclic AMP synthesis in the intact leukocytes over the basal activity. One-way analysis of variance showed that the mean PGE_1-stimulated activity in the patient groups did not differ significantly from that in the normal controls.

In vitro addition of NE (10^{-4} M) produced an approximately 1.5-fold increase in net ^{3}H-cyclic AMP synthesis in normal controls. The mean activity observed in the patient groups, however, was significantly lower than that in the controls, as determined by one-way analysis of variance (table 1). This suggested that the ^{3}H-cyclic AMP synthesis produced by NE, although lower in the patient population, could not distinguish between patients with affective illness and schizophrenic patients (p=n.s., Scheffe's test). Synthesis of ^{3}H-cyclic AMP by human leukocytes was also measured after addition in vitro of IP (10^{-4} M). This addition produced an approximately 2-fold increase in net ^{3}H-cyclic AMP synthesis above the baseline.

One-way analysis of variance indicated significant differences between the various subject groups (table 1). Further analysis by Scheffe's test indicated that patients diagnosed as having major unipolar depressive disorders showed significantly lower IP-stimulated activity than normal controls ($p<.001$) and schizophrenic patients ($p<.05$). Patients with bipolar mania were significantly different from normal controls but did not differ from the unipolar depressed patients. Schizophrenics did not differ significantly from normal controls.

DISCUSSION

Studies of adrenergic receptor function in affective illness with the use of platelet adenylate cyclase and its responsiveness to PGE_1 and NE have been reported

by Wang and associates (19) and Murphy and associates (21). The platelet responses observed in depressed patients were found to be indistinguishable from those of normal controls. The responses produced by NE in human platelets are primarily α-adrenergic, whereas elevation of cyclic AMP synthesis produced by NE in the brain has been reported to result primarily from β-adrenergic receptors, although α-receptors may also be involved (19–21). Studying α-adrenergic receptor response in human platelets to evaluate a generalized abnormality in the adrenergic response may be of value. However, in the light of the negative results obtained for platelet adenylate cyclase, it may be useful to perform such studies in a peripheral tissue in which alterations in cyclic AMP synthesis are produced by responses of the β-adrenergic receptors.

Our leukocyte studies indicated that there was no difference in either the basal activity or the PGE_1-stimulated activity among the groups studied. NE-sensitive leukocyte adenylate cyclase activity was significantly lower in patients than in normal controls, and IP-stimulated activity was significantly lower in the depressed group than in controls and schizophrenic patients. Although these results generally suggest a reduced sensitivity of β-adrenergic receptors in the leukocytes of patients with affective illness, we did not expect to find significantly lower NE-sensitive leukocyte adenylate cyclase activity in schizophrenics than in controls.

Several explanations could be offered for this observation. Norepinephrine is both an α- and a β-adrenergic agonist, and the net increase in cyclic AMP synthesis produced by NE in human leukocytes is a cumulative response of both α- and β-adrenergic receptors (22, 23) because some α-receptors may be present in human leukocytes (15). Since the function of α-adrenergic receptors is usually opposite to that of β-adrenergic receptors, a reduction in cyclic AMP synthesis in the leukocytes produced by NE in the patient groups could be caused by either subsensitivity of β-adrenergic receptors, which stimulate cyclic AMP synthesis, or hypersensitivity of α-adrenergic receptors, which inhibit the synthesis of cyclic AMP. It is possible that the decreased response produced by NE in leukocytes reflects hypersensitivity of α- and normal sensitivity of β-adrenergic receptors in schizophrenic patients and subsensitive β- and normal α-adrenergic receptors in affectively ill patients. The net response produced by NE in either situation is a reduction in the cyclic AMP synthesis.

Further observation that ^{3}H-cyclic AMP synthesis produced by IP, which is a much more specific β-adrenergic agonist, is not significantly different in schizophrenic patients and controls tends to support the above assumption. Thus, whereas increased α-adrenergic receptor sensitivity may be associated with schizophrenic illness, a reduction in β-adrenergic receptor sensitivity may be involved in affective illness. It is also possible that a common biologic abnormality of β-adrenergic receptor deficiency, not specific to either disease, is associated with altered behavior.

Our results suggesting a reduction in the β-adrenergic receptor sensitivity in depressed patients are similar to those reported by Prange and associates (24), who observed diminished systolic pressor response to NE in depressed patients. However, these findings are contradictory to those reported by Ghose and associates (25) and Friedman (26), who observed an increased pressure response to intravenously administered amines. It may be difficult to compare our studies, which determine an in vitro biochemical response in an isolated cell preparation, to their studies, which measured an in vivo physiologic response. Furthermore, the sensitivity of receptors developed in different areas may be different and unrelated, as reported by Friend and associates (27).

Some reports suggest that there is a significant decrease in IP-stimulated cyclic AMP synthesis in patients suffering from bronchial asthma (11–13). Recently, it has been reported that some depressed patients also suffer from bronchial asthma and that they benefit from treatment with lithium (28). Although this report was based on two cases, one of the authors has found similar results in additional patients (S. J. Nasr, personal communication). The relationship of bronchial asthma, depression, and lithium response to adenylate cyclase is not clear, but these observations may provide useful clues for future investigations on the etiology of depression.

The reported results of reduced β-adrenergic receptor sensitivity in depression need to be investigated further by other methods, such as direct quantitation of β-adrenergic receptor sites in human leukocytes by binding techniques with radiolabeled antagonists such as ^{3}H-DHA. This preliminary study needs to be further investigated and replicated by other researchers.

The Role of Plasma Amine Oxidase, Platelet Monoamine Oxidase, and Red Cell Catechol-*O*-Methyl Transferase in Severe Behavioral Reactions to Disulfiram

BY LESLIE F. MAJOR, M.D., DENNIS L. MURPHY, M.D., ELLIOT S. GERSHON, M.D., AND GERALD L. BROWN, M.D.

The authors assayed platelet monoamine oxidase (MAO), plasma amine oxidase (AO), and red cell catechol-O-methyl transferase (COMT) in 32 male alcoholics before they began disulfiram treatment. Seven subjects developed psychotic reactions to disulfiram; these 7 had significantly lower pretreatment MAO and AO levels and significantly higher COMT than the patients who had no adverse reactions to disulfiram, which suggests that severe behavioral reactions to disulfiram are associated with differences in enzyme activities.

FACTORS MOST COMMONLY used to explain individual differences in drug responses include variations in the absorption, distribution, metabolism, or excretion of a drug (1). There are also psychological determinants of pharmacological response, such as the initial state of individual arousal determining the response to a drug acting on arousal mechanisms or preexisting mood determining the affective response to a mood-altering drug (2–4).

More recently a growing number of unusual drug responses have been shown to be genetically determined, for example, prolonged apnea secondary to succinylcholine in patients with genetically atypical pseudocholinesterases (5), polyneuritis as a toxic complication of isoniazid in patients with genetically determined slow acetylation (6, 7), and hemolysis secondary to primaquine in individuals with glucose-6-phosphate dehydrogenase deficiencies (8). Prior to the discovery of the genetically determined enzyme abnormality involved, the above-mentioned unusual drug reactions were called idiosyncratic reactions. In this paper we look at another idiosyncratic reaction, disulfiram psychosis, in an attempt to find some common underlying mechanism that may be responsible for these atypical drug reactions.

Disulfiram was first introduced in the late 1940s after it was noted to cause an adverse reaction when alcohol was ingested (9). This adverse reaction was shown to be the result of disulfiram's inhibition of aldehyde dehydrogenase, an enzyme necessary for the metabolism of alcohol (10, 11). Disulfiram has also been shown to inhibit other enzymes (12), particularly dopamine beta hydroxylase, the enzyme responsible for the conversion of dopamine to norepinephrine (13). Initial widespread use of the drug resulted in the reporting of a high incidence (30%) of psychotic reactions (14, 15). Further studies revealed that the psychotic reactions were dose related, more likely to develop in patients who developed other side effects such as lethargy and fatigue (15), and more common in individuals with depressive, borderline, or schizophrenic diagnoses (16).

We have previously shown differences in the enzymes of monoamine metabolism in individuals with affective disorders (17, 18) and schizophrenia (19). The hypothesis that differences in one or more of the enzymes of monoamine metabolism might be involved in psychotic reactions to disulfiram led to the present retrospective review.

METHOD

Our study included 32 patients from an alcohol rehabilitation unit that used disulfiram in its treatment program. They were part of a larger study investigating platelet and plasma amine oxidase (AO) in 99 alcoholic individuals (20). Because of limited resources, erythrocytes for the assay of catechol-*O*-methyl transferase (COMT) were collected but not routinely assayed on all 99 subjects. Instead 32 individuals were selected as a pilot group and all erythrocyte samples on these individuals were assayed for COMT. All patients with adverse reactions to disulfiram (N=12) were included in order to test our hypothesis. The remaining 20 individuals were randomly selected from the larger group in order to arrive at 16 individuals who had received disulfiram in doses of 500 mg/day and 16 individuals who had received 250 mg/day to test for

Presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8–12, 1978. Received May 5, 1978; revised Nov. 27, 1978; accepted Dec. 15, 1978.

Dr. Major is Staff Psychiatrist, and Dr. Murphy is Chief, Clinical Neuropharmacology Branch, National Institute of Mental Health, where Dr. Gershon is Chief, Section on Psychogenetics, and Dr. Brown is Staff Psychiatrist, Biological Psychiatry Branch. possible dose-dependent effects of disulfiram on COMT. Samples had been collected both before and after disulfiram treatment.

The patients' age range was 18 to 50 with a mean (± SEM) of 33±1.9 years. All patients were free of cardiovascular, renal, or liver disease and met *DSM-II* criteria for habitual or episodic excessive drinking and Spitzer and associates' Research Diagnostic Criteria (RDC) (21) for alcoholism. All 32 patients had been abusing alcohol for more than 2 years (range=2-20+) and had a score of greater than 10 on the Michigan Alcoholism Screening Test (22), a series of 24 questions designed to gauge the degree of a patient's alcohol abuse. Their mean score was 15.6, out of a possible 24; 6 is considered the cut-off score indicating a significant alcohol problem. None of the patients had a diagnosis of psychosis or organicity according to *DSM-II* or the RDC.

All 32 subjects were drug free, except for alcohol, for at least 14 days before admission to the hospital, and while in the hospital they were drug free except for disulfiram. All other drugs were carefully avoided during the study.

Within 5 days of admission and before disulfiram was started, venous blood samples were collected. Platelet-rich plasma (PRP) was prepared by sequential 10-minute centrifugations at 175 and 300 *g*; the PRP was removed and pooled after each centrifugation and then frozen at −70°C after an aliquot was removed for platelet counts. The sample remainder was then centrifuged at 8000 *g* for 10 minutes; plasma was removed and stored at −70°C and 2 ml of packed red blood cells removed and frozen at −70°C. Platelet and plasma amine oxidase activity were determined by Murphy and associates' method (23) and red cell COMT by the method of Jonas and Gershon (24).

After the initial venipuncture, 16 individuals received disulfiram, 500 mg/day, and the remaining 16, 250 mg/day. All medication was crushed (in order for patients to be blind as to amount received) and given in milk under observation to insure compliance. Every patient was evaluated daily by the staff psychiatrist for the initial 6-week period of disulfiram treatment as part of the rehabilitation program. The patients who developed psychiatric reactions to disulfiram were evaluated and diagnosed by a psychiatrist who was blind to the medication they had received and to the pretreatment biochemical data. Repeat blood samples were collected at 3 weeks and 6 weeks.

RESULTS

Individual pretreatment enzyme values for all 32 subjects are listed in table 1. Both plasma amine oxidase activity and platelet monoamine oxidase activity were significantly lower in those individuals who later developed psychotic reactions to disulfiram ($p<.01$, Student's two-tailed t test) (table 2). Similar results were found when the larger group (N=99) was examined ($p<.001$, Student's two-tailed t test). Pretreatment red cell COMT was significantly higher in those individuals who developed psychotic reactions ($p<.001$, Student's two-tailed t test) (table 2). The five individuals who developed minor reactions to disulfiram tended to have lower platelet and plasma amine oxidase activity and higher COMT activity, but these differences did not reach statistical significance (table 2). Age, severity of drinking, chronicity of drinking, and time of last drink were not significantly different in the groups with and without reactions to disulfiram and were not significantly correlated with MAO, AO, or COMT activities.

Using discriminate function analysis, red cell COMT was the best single pretreatment indicator of future behavioral side effects during disulfiram treatment, correctly placing 22 of the 32 individuals (68.8%)

into one of the three groups: major reaction, minor reaction, or no reaction. When platelet and plasma amine oxidase were added into the discriminate function analysis, 25 of the 32 individuals (78.1%) were correctly categorized. Adding in age as a fourth variable had no effect. A ratio was formed by dividing an individual's COMT value by the product of his two amine oxidase values (platelet and plasma), in order to obtain a single value that would represent an individual's capacity for methylation versus oxidation. The resulting ratio was able to correctly place 28 of the 32 individuals (87.5%) into one of the three groups (table 2). Figure 1 is a point graph of individual ratios in the three groups.

Seven of the 99 individuals who were admitted to the unit developed psychotic reactions to disulfiram. Five of these 7 were classified according to *DSM-II* as toxic-schizophrenic psychoses, one as a toxic-manic psychosis, and one as a toxic-depressive psychosis by a psychiatrist blind to the study. All 7 individuals had been on 500 mg/day of disulfiram, an incidence significantly different from that of the patients who received 250 mg/day of the drug ($p<.01$, Fisher exact test). Five additional individuals had developed nonpsychotic behavioral changes that responded to a reduction in disulfiram dosage. Four of these reactions consisted of fatigue and lethargy and the fifth of mild confusion and difficulty concentrating. Two of these individuals had been taking 500 mg/day and the remaining 3 were taking 250 mg/day. As a check on randomization in the different dosage groups, a medium split was done for each set of pretreatment enzyme values and a chi square done to test for equal distribution in the two dosage groups. No significant differences were found in the two dosage groups for the three enzymes measured. After 3 and 6 weeks on di-

sulfiram, MAO, AO, and COMT were not significantly different from baseline, indicating that disulfiram, 250 or 500 mg/day, apparently had no direct effect on these enzymes.

DISCUSSION

Significant monozygotic versus dizygotic twin differences and sibling-sibling correlations have been found in humans for platelet and plasma amine oxidase and COMT activity in plasma and blood cells, indicating genetic influence (25–27). There are also similar data that indicate genetic contributions to schizophrenia and bipolar affective disorder (28). Individual differences in neurotransmitter-related enzymes would provide one possible mechanism for mediating genetic vulnerability for these disorders. COMT has been found by some investigators to be elevated in schizophrenia (29–31) and both unipolar and bipolar affective disorder (32), but other studies have failed to confirm these findings (33–37). In the case of platelet MAO, many investigators have found decreased activity in schizophrenics (19, 38–59) and bipolar affective disorder (17, 41, 44, 60). Other investigators, however, have not confirmed these results (51, 61–71). The reason for these discrepant results is as yet unclear. Plasma amine oxidase has not been so intensely studied, and in the two available studies (72, 73) no differences in plasma amine oxidase have been reported between depressed or manic patients and controls.

Enzyme measurements in other areas of medicine have proved to be of value in predicting side effects from drugs (e.g., isoniazid toxicity in patients with low acetylase activity and succinylcholine supersensitivity associated with low plasma pseudocholinesterase activity). The present study shows that platelet and plasma amine oxidase activity and red cell COMT activity may be of value in predicting behavioral side effects from disulfiram administration. Since these enzymes are not necessary for the metabolism of disulfiram, it is unlikely that differences in enzyme activity resulted in differences in circulating levels of disulfiram to account for the adverse reactions. Disulfiram, however, is a potent inhibitor of dopamine beta hydroxylase and would be expected to result in a decrease of norepinephrine and an increase of dopamine in noradrenergic neurons, as has been shown in animals (74). We have previously shown that patients with psychotic reactions to disulfiram had significantly lower pretreatment cerebrospinal fluid levels of dopamine beta hydroxylase than patients with no adverse reactions (75), which suggests that the noradrenergic system is involved in the emergence of psychotic symptomatology. It is unlikely that the decreased formation of norepinephrine is responsible since MAO inhibitors, which would be expected to increase central norepinephrine, are associated with an increase in disulfiram-induced psychosis (76, 77).

The other effect of inhibiting dopamine beta hydroxylase is to cause a build-up of dopamine in noradrenergic neurons (74). Stein and Wise (78) have postulated a similar mechanism in schizophrenia—a genetic defect in dopamine beta hydroxylase resulting in a build-up of dopamine in noradrenergic neurons that could then be auto-oxidized to 6-hydroxy dopamine, a neurotoxin. Some investigators (19, 38–59) have also shown patients with schizophrenia to have low platelet MAO. If low platelet MAO is a reflection of low MAO activity in other tissues, such as the brain, we could speculate a relationship between MAO activity and the ability to metabolize dopamine in noradrenergic neurons, with low MAO activity resulting in a greater build-up of dopamine in noradrenergic neurons. The results of the present study are consistent with this general formulation. Individuals who developed disulfiram psychosis had significantly lower platelet MAO and plasma AO activity, possibly reflecting a generalized decrease in amine oxidizing capacity. They also had significantly elevated red cell COMT activity. Again, there is no evidence that red cell COMT activity is correlated with brain COMT activity, although such evidence does exist for other enzymes (79, 80). The most intriguing hypothesis stemming from the present study is that the ratio of various metabolizing enzymes, i.e., those involved in methylating, oxidizing, and β-hydroxylating, is important in the manifestation of psychotic or toxic symptomatology. Both MAO and dopamine beta hydroxylase have been shown to be important degradative enzymes necessary to metabolize trace amines and abnormal metabolites (81, 82). Also, COMT in conjunction with other

methylating enzymes may produce abnormal metabolites that might result in psychotic symptomatology if they are not rapidly metabolized (83). An individual's ability to tolerate an amine load, tolerate a drug that alters the biogenic amines, or even tolerate stress, may in part depend on the ratio of methylating ability to oxidizing or β-hydroxylating ability. The validity of such a hypothesis awaits further investigation.

Reduced Cyclic AMP Production in the Blood Platelets from Schizophrenic Patients

BY MARIAN S. KAFKA, PH.D., DANIEL P. VAN KAMMEN, M.D. AND WILLIAM E. BUNNEY, JR., M.D.

The authors assessed α-adrenergic receptor function in blood platelets from chronic schizophrenic patients and normal control subjects. The number of receptors was measured by the specific binding of the α-adrenergic antagonist [^{3}H]dihydroergocryptine to the platelets. A physiological response of the platelets to agonist occupancy of the α-adrenergic receptors was measured by the norepinephrine inhibition of prostaglandin E_1 (PGE_1)-stimulated cyclic AMP (cAMP) production. cAMP production in male schizophrenic patients was lower than in normal male subjects. α-Adrenergic receptor function was similar in patients and normal control subjects of both sexes. Normal male subjects had about 1.5 times the number of α-adrenergic receptors as normal females and generated about 1.8 times the quantity of PGE_1-stimulated cAMP.

THE IMPLICATION of catecholamines in the pathogenesis of schizophrenia (1, 2) suggests that an assessment of catecholamine neurotransmitter function in schizophrenic patients might be of interest. The α-adrenergic receptors on human platelets (3) share pharmacological properties with α-adrenergic receptors from brain and other tissues (4–6), and norepinephrine inhibition of prostaglandin E_1 (PGE_1)-stimulated cyclic AMP (cAMP) production in platelets measures the physiological response to occupancy of the α-adrenergic receptors (3).

Platelets isolated from a fresh blood sample were used to measure the specific binding of [^{3}H]dihydroergocryptine (^{3}H-DHE) to platelet membranes and the production of cAMP under basal and stimulated conditions in whole platelets (3). The reliability of the measurements over time was assessed in controls on two separate blood samples. The correlation coefficient between the two values obtained for PGE_1-stimulated cAMP production in 16 subjects was 0.561 ($p<.05$) and for ^{3}H-DHE binding in 7 subjects was 0.781 ($p<.05$). At the concentration of ^{3}H-DHE used to measure specific binding (35 nM, the K^d for ^{3}H-DHE binding), a change in binding would indicate an alteration either in the number of receptors or in the affinity of the receptors for ^{3}H-DHE (3). Because the affinity of the α-adrenergic receptor for ^{3}H-DHE is similar in normal and schizophrenic individuals (unpublished data), ^{3}H-DHE binding measures the number of α-adrenergic receptors.

Eleven male and 9 female inpatients on a schizophrenia research unit took part in the study. All patients were diagnosed schizophrenic with four or more symptoms of schizophrenia according to the International Pilot Study of Schizophrenia (7). According to Research Diagnostic Criteria (8) 8 of 11 male patients were schizophrenic, and 3 were schizo-affective; 3 of 9 female patients were schizophrenic, and 6 were schizo-affective. The mean (ISE) age, duration of illness, and length of hospitalization were not significantly different in male and female patients (24.9±2 years, 4.4±1.4 years, and 30±18 months, respectively, and 23.4±2 years, 3.2±0.8 years, and 11.3±5, respectively).

The control subjects were blood bank donors. As there was no correlation between the age of control subjects and any of the biological variables measured, the control subjects used ranged in age from 18 to 65 years (mean=45 years).

RESULTS

Male patients had the same number of α-adrenergic receptors as male control subjects (table 1) but showed a decrease in cAMP production of 33% under basal conditions and 37%–44% with PGE_1 stimulation. The percentage of norepinephrine inhibition was similar in both groups (table 1, figure 1).

Female patients and their sex-matched controls had the same number of α-adrenergic receptors and the same level of cAMP production. The percentage of norepinephrine inhibition of PGE_1-stimulated cAMP production was the same in both groups (table 1).

Male control subjects had about 1.5 times as many α-adrenergic receptors on their platelet membranes as female control subjects. cAMP production in the plate-

TABLE 1
cAMP Production and ^{3}H-DHE Binding in Platelets of Schizophrenic Patients and Their Sex-Matched Controls

Sex and Diagnosis	cAMP Production (pmol/mg protein per minute)[a]								^{3}H-DHE Binding[b] (fmol/mg protein)		
	Number of Subjects	No Drug Mean	No Drug SE	PGE_1 Mean	PGE_1 SE	PGE_1+Norepinephrine Mean	PGE_1+Norepinephrine SE	%[c]	Number of Subjects	Mean	SE
Male											
Normal control	21	5.8	0.6	58.2	7	26.5	3	54	17	179.9	21
Schizophrenic	11	3.6[d]	0.5	32.6[e]	5	16.5[d]	3	49	11	187.4	24
Female											
Normal control	17	4.6	1	31.9	5	13.7	2	57	12	122.2	11
Schizophrenic	9	4.6	0.8	28.4	5	13.1	3	55	9	191.2	35

[a]The concentration of PGE_1 was 5×10^{-8} M and of norepinephrine was 5×10^{-5} M; for stimulated cAMP production male controls differed significantly from female controls with and without norepinephrine ($p<.01$ and $p<.005$, respectively).
[b]Binding data were not available for all controls for whom cAMP data were measured; male controls differed significantly from female controls ($p<.05$).
[c]Norepinephrine inhibition of PGE_1-stimulated cAMP production.
[d]Male schizophrenics differed significantly from their controls ($p<.05$).
[e]Male schizophrenics differed significantly from their controls ($p<.025$).

FIGURE 1
cAMP Production in Male Schizophrenic Patients and Control Subjects[a]

[a]cAMP values are means of triplicate measurements under three conditions: with no drug, with PGE_1 (5×10^{-8} M) and with PGE_1 (5×10^{-8} M) and norepinephrine (5×10^{-5} M). The differences are significant at $p<.05$ for PGE_1-stimulated cAMP production and at $p<.025$ for basal and norepinephrine-inhibited PGE_1-stimulated cAMP production.

lets of male control subjects was the same as that of female control subjects under basal conditions, but PGE_1-stimulated cAMP production was almost twice as great. The percentage of norepinephrine inhibition of PGE_1-stimulated cAMP production was similar in male and female control subjects (table 1).

DISCUSSION

Because normal male control subjects have more α-adrenergic receptors and greater PGE_1-stimulated cAMP production than normal female control subjects, the schizophrenic patients were compared with their sex-matched controls. Whether sex hormones contribute to the observed differences between males and females requires further study. α-Adrenergic function does not appear to be abnormal in the platelets of schizophrenic patients as the number of α-adrenergic receptors and the percentage of inhibition by norepinephrine of PGE_1-stimulated cAMP production is the same in the patients and their sex-matched controls.

Male, but not female, schizophrenic patients produce less cAMP in their platelets under basal as well as stimulated conditions. The low level of cAMP in male, but not in female, schizophrenic patients may indicate that the level of cAMP production is unrelated to schizophrenia. On the other hand, if the decrease in cAMP production is related to schizophrenia, the finding would lend support to the hypothesis that schizophrenia is not a single disease but a group of diseases with common clinical features and different etiologies (9). Within the disease spectrum decreased cAMP production might characterize a form of schizophrenia manifested only in males.

The specificity to schizophrenia of decreased platelet cAMP production can be assessed by comparing platelet cAMP production in the platelets from schizophrenic patients and patients with other psychiatric disorders.

Some factors that could contribute to the decreased cAMP production observed in male schizophrenic patients were considered. Neither the age, the duration of illness, nor the length of hospitalization in male or female schizophrenic patients showed any correlation with the cAMP level. It seems unlikely that neuroleptic treatment is responsible for the decrease in cAMP production for several reasons. Chlorpromazine (10^- M) incubated for 5 minutes in vitro with platelets from four normal individuals did not alter cAMP production. In patients on neuroleptic therapy most of the platelets would not have been exposed to the drugs since the patients had been drug-free for at least 2 weeks prior to the study and platelets have a turnover time of about 10 days (10). Finally, the female patients whose demographic characteristics corresponded roughly with those of the males and who had received as well as could be determined, comparable amounts of neuroleptics, showed no such decrease.

The possibility that low cAMP production might be due to an inherited trait could be investigated by mea

suring whether cAMP production in the relatives of male schizophrenic patients is significantly less than that in normal control subjects.

Murphy and associates (11) have shown that norepinephrine inhibits PGE_1-stimulated cAMP production in platelets from normal subjects and patients with affective illness treated with lithium carbonate. PGE_1-stimulated cAMP production was reduced in the lithium-treated patients but was not measured in patients who were not receiving the drug. Pandey and associates (12) found elevated PGE_1-stimulated adenylate cyclase activity in 5 acute schizophrenic patients and no difference between PGE_1-stimulated adenylate cyclase activity in control subjects and 4 chronic schizophrenic patients. Platelets from male and female subjects were not studied separately. Pandey and associates (13) found no change in basal, PGE_1-stimulated, or α-adrenergic-mediated inhibition of adenylate cyclase activity in platelets from patients with affective illness; however, they found a diminution in β-adrenergic-mediated stimulation of adenylate cyclase activity in leukocytes from patients with affective illness. Abdulla and Hamadah (14) observed that PGE_1 synthesis was very low in platelets from schizophrenics compared with platelets from normal controls or patients with affective illness. Low concentrations of prostaglandins (or prostacyclins), in addition to diminished responsiveness of cAMP production to prostaglandin stimulation, might result in an even more profound cAMP deficit in the platelets of male schizophrenic patients. Peroutka and associates (15) showed that in the rat most neuroleptics, including chlorpromazine, had α-adrenergic antagonist activity. In the current study chlorpromazine has no α-adrenergic antagonist activity against norepinephrine-inhibited PGE_1-stimulated cAMP activity in human platelets.

In many cells, including platelets and neurons, cAMP increases, through phosphorylation, the activity of cell proteins (16, 17). It is possible that the decrease in cAMP production is limited only to platelets. Perhaps decreased cAMP production, such as that seen in the male schizophrenic patients, is a more general phenomenon resulting in deficits in neuronal systems etiologically important to schizophrenia.

EDITORIAL

Care of the Chronically Mentally Ill—Still a National Disgrace

WRITING IN THIS SPACE in 1973, Robert Reich, M.D., called the care and treatment of the severely and chronically mentally ill a national disgrace (1). Since then things have grown worse.

They have grown worse because, while deinstitutionalization has proceeded, states still have not found a way to enable monies to follow patients from state hospitals to community settings and because with the recent fiscal crunch, all levels of government have again placed a lower priority on mental health than on education, highways, police, fire, and sanitation. They have grown worse because with the budgetary constraints and the threat of loss of accreditation to state hospitals, states have predictably shunted money into state rather than community settings and, because with the current emphasis on cost containment in health care, chronic patients in need of long-term supportive care and treatment have been the first to be discriminated against by reimbursement mechanisms such as Medicaid. Finally, they have grown worse because despite the lesson learned over the past 20 years that chronic patients need a vast array of supportive services including housing, income, education, and vocational and social rehabilitation, in addition to a full range of medical and psychiatric services, there are only isolated examples in the United States of programs providing such comprehensive care.

Historically, many attempts have been made to care for the chronically mentally ill. A succession of institutions have been proposed as *the* solution to the problem. Community mental health centers were designed to replace state hospitals, which replaced almshouses and workhouses, which replaced prison-like outhouses. Each "solution" has failed to solve the problem. And the latest fashion, community care, will join their company if it is allowed to proceed in its present form. It may be a debatable question (2, 3) whether or not state hospitals have improved over the last 20 years, despite the fact that they now house fewer than one-third their previous population and have vastly improved staffing, now approaching a 1:1 ratio. But there is no question that the current care provided to chronic patients in the community, whether deinstitutionalized or never admitted, is inadequate.

In 1975 APA charged an Ad Hoc Committee on the Chronic Mental Patient to study the issues and to propose a national public policy. The committee commissioned eight new studies on key areas: where the chronic patients are, their needs, the programs that help them, the obstacles that impede effective treatment, the economic issues, the legal issues, what levels of government should have what responsibility, and the pros and cons of case management. These studies served as a basis for a national invitational Conference on the Chronic Mental Patient (4), held in January 1978 in conjunction with the President's Commission on Mental Health. A report emanating from the conference, in the form of a call to action for a public policy, has been reviewed and approved by all components of the APA (district branches, committees, Councils, the Assembly, and the Board of Trustees) and is published in this issue of the *Journal* as a position statement.

The committee sought to achieve consensus but in certain instances took controversial positions, which may seem provocative to some readers. For instance, the statement calls for an end to the government's conflict of interest in both

0002-953X/79/06/0688/02/$00.35 © 1979 American Psychiatric Association

operating and contracting for mental health services (at federal, state, and local levels); it calls for *local* government to designate who shall provide services for chronic patients. It also calls for private practitioners to be encouraged in caring for this population; for the adoption of a case management approach rather than case managers; and for an end to discriminatory reimbursement for long-term treatment and chronic care, coincident with the introduction of innovative methods (e.g., a voucher system) to provide appropriate care settings such as halfway houses and apartments for patients, rather than nursing or board-and-care homes.

The bulk of the statement, while sweeping, detailed, and comprehensive, will probably not incur dissent, for it addresses in detail the measures needed to reverse the current situation. It suggests that financing may be the key to most of the problems encountered by chronic patients. More money is not necessarily needed, but existing monies certainly must be redeployed from restrictive, inappropriate settings to a range of graded opportunities. The statement also suggests that discrimination against the chronically ill in health insurance, housing, vocational rehabilitation, and employment needs to be reversed. It redefines roles for all levels of government: the federal government to become responsible for national priorities and guidelines; state governments for regional priorities and plans; local governments for designation of providers; and the actual services provided by contract by the smallest entities possible (e.g., catchment areas). It challenges psychiatry to engage in two previously neglected areas: training and research related to chronic illness. The statement recommends that psychiatric residencies incorporate experience with the chronically mentally ill in community settings and that research efforts be directed toward patient outcome studies, comparing different treatment modes and analyzing model service systems. It also encourages psychiatrists and psychiatry to become involved in planning and delivering services to chronic patients, even though these patients' primary problem may involve disability, not disease. And finally—but most important in the long run—it calls for a vast program of professional and public education regarding chronic mental illness and disability, without which none of the above will be realized.

The statement was intended as a comprehensive blueprint for public policy. It will be successful only if it is translated into effective action through legislation, governmental procedures, and professional initiative. While deriving *from* APA, it is not solely *of* APA, and it will become a reality only if all psychiatrists and all mental health workers and professional organizations fight for the adoption of each of its broad policies and detailed recommendations.

BRIEF COMMUNICATIONS

State and Trait in Psychiatric Practice

BY IRL EXTEIN, M.D., AND MALCOLM B. BOWERS, JR., M.D.

The authors present a schema for conceptualizing psychiatric illness in terms of state and trait disorders. These disorders are relatively independent components, one or both of which can be present in one patient. They usually require treatment by different methods. State disorders, such as schizophrenic psychosis, mania, and depression, are time-limited and autonomous and respond better to pharmacological than psychosocial therapy. Trait disorders, such as neurotic and characterological disturbances, are long-lasting and respond better to psychosocial therapies. The authors discuss the implications of this schema for the integration of pharmacological and psychosocial treatments.

WE PROPOSE a schema for conceptualizing psychiatric illness that has implications for teaching and therapy. The basic approach to clinical syndromes embodied in our schema is implicit in much of contemporary psychiatric practice. It is our aim to refine and make explicit this approach by organizing it into a schema around the focal concepts of state disorder and trait disorder.

So far as we can determine, the state-trait dichotomy was first used by Spielberger (1), who distinguished anxiety in the present (state anxiety) from the frequency of anxiety in the past (trait anxiety). Our own interest in this distinction (2) stems from clinical work and neurobiological concepts of plasticity (3). These have led us to use the terms "state" and "trait" to refer to two qualitatively different processes. The concept of "state" is, in our schema, related to a plasticity in biobehavioral systems that allows reversible and relatively stereotyped behavior and which accommodates biobehavioral rhythms, central nervous system activation, depression, and the like. It has been called "activational" plasticity. The concept of "trait" is related to a different kind of plasticity that has been called "organizational" and refers to that continuing process of interaction between genetic endowment and environment (with critical periods implied) that results in organismic development and maturation. These concepts were originally developed in the context of animal research dealing with the effects of hormones on sexual gender differentiation (organizational plasticity) and mating behavior (activational plasticity) (3, 4). Our attempt here is to propose their relevance to clinical psychiatry.

Received April 29, 1978; accepted July 18, 1978.

THE STATE-TRAIT SCHEMA

We consider disorders of state and trait to be relatively independent components of psychiatric illness (2) that may be present alone or together in one individual. They must to a large extent be diagnosed separately and treated by different techniques. "State disorder" refers to those qualitatively different mental conditions which tend to be time-limited and autonomous in that, once present, they are relatively insensitive to environmental input. They respond poorly to verbal or other psychosocial treatment but usually respond to medication or other somatic treatment (5–7). Specifically, state disorders include schizophrenic and other functional psychoses, mania, major depression, severe anxiety, acute organic brain syndrome, and seizures. Most of these state disorders probably involve a variety of environmental stressors acting on genetic or other biological vulnerability (8–12). "Trait disorder" refers to those dysfunctional qualities which individuals tend to develop and carry throughout life and which become manifest as predictable patterns of

0002-953X/79/06/0690/04/$00.45 © 1979 American Psychiatric Association

interaction and response to stress. Such patterns tend not to be responsive to medication but respond better to psychosocial treatment (5–7). Trait disorders include neurotic and characterological disturbances, including subnormal intelligence, and seem to be learned as a result of the interplay between innate characteristics and parental and social experience (6).

It is important to consider how this schema can be used over time, because psychiatric illnesses are not static entities and treatment approaches must shift. The first question to ask in evaluating a patient might be, "Is a state disorder present?" If the answer is "yes," then medication is indicated. As a rule, we do not think that effective psychosocial intervention can be made in a patient with a state disorder. Patients can not be "talked" out of state disorders, although doctor-patient interaction is critical to patient care in the early stages of state disorders, such as psychosis or depression, for example. Our point is that the definitive treatment of state disorders is not primarily psychosocial. Because the symptoms of a state disorder can obscure or highlight excessively the usual personality traits of an individual, the possibility that a trait disorder exists cannot be accurately assessed while a state disorder is present. Even if a clinically significant trait disorder does exist in an individual with a state disorder, one must usually wait to treat the trait disorder until the state disorder has cleared. For example, it is difficult to assess or explore insecurities about interpersonal relationships in a patient who is manic or has a paranoid psychosis. Once the state disorder has cleared, or if a state disorder was never felt to be present, the question can be asked, "Is a trait disorder present?" This aspect of diagnosis or evaluation is usually made by examining the patient's patterns of interaction with significant persons in his or her life. If the answer is "yes" then the appropriate psychosocial intervention can begin.

The role of psychosocial treatments in psychiatry is controversial, and the place given them in our schema requires clarification. In discussing state disorders, we are not saying that a patient with a schizophreniform psychosis, for example, does not respond to some degree to the environment and the people in it or that the content of the psychosis cannot at times have authentic personal meaning. Rather, we are saying that the psychotic process itself cannot be significantly altered by psychosocial means (5–7, 13). In addition, while stating that trait disorders should be treated by psychosocial methods such as psychotherapy, we acknowledge that the efficacy of psychotherapy has been difficult to document (7, 14).

We do not mean to neglect the importance of life stress and developmental issues. These components can be considered as separate dimensions of psychiatric illness and are compatible with our state-trait distinction. Stress can certainly precipitate a state disorder in an individual genetically or otherwise biologically vulnerable (15, 16), as when a loss precipitates a depression or the first year away from home is associated with the onset of schizophrenic psychosis. However, the importance of life stress cannot be adequately assessed or taken up therapeutically until the state disorder has been treated. Stress can also exaggerate personality trait disorders. In some disturbed patients a pathological state or trait disorder is not present, and the disturbance can be best described as a situational adjustment or developmental crisis. In such cases psychosocial therapies, including crisis intervention, are usually indicated (17).

Disorders of state and trait can mimic each other and make the choice of proper treatment modality difficult. For example, the behavior, mood, and thinking of patients suffering from the borderline syndrome often fluctuate markedly (18). Sometimes psychotropic medications are tried when, in fact, a drug-responsive state is not present and the fluctuations are best treated as part of the character disorder by psychosocial means. At other times drug-responsive mood disorders, psychoses, or seizures in a patient with the borderline syndrome are missed because of the continuing and obscuring presence of a severe character disorder. These examples underline the importance of accurate knowledge of a patient's baseline personality traits in diagnosing a superimposed state disorder and emphasize the importance of therapeutic medication trials in ambiguous cases.

The use of this schema might help foster complementarity of assessment and treatment ideologies in the clinical setting. The issue of drugs versus psychotherapy may be in large measure a false dichotomy. More relevant to clinical care are issues involving the use of the proper treatment modality for the appropriate component problem at the proper time in the course of a psychiatric illness. For example, consider a patient with a severe depression, of the type we define as a state disorder (19), superimposed on chronic marital difficulties. This patient would probably benefit little from psychotherapy initially but might benefit a great deal once his or her depressive state had been treated with antidepressant medication. Recent work with women suffering from unipolar depressions supports the notion of state and trait disorders as independent target problems requiring different treatment. Antidepressants have been shown to be more useful than psychotherapy in alleviating depressive symptoms and maintaining symptomatic remission (5, 20). However, psychotherapy has been found to be more useful than antidepressants in improving social functioning after treatment of the acute depression with medication (21).

The use of this two-dimensional schema cuts across conventional one-dimensional diagnostic categories. The neuroses and character disorders are conceptualized as trait disorders, although again with the caveat that the existence of neurotic traits does not exclude the possibility that a state disorder may develop and require treatment. Mood disorders, both bipolar and unipolar, are conceptualized as state disorders. However, patients with mood disorders may suffer from

character pathology or social maladjustment that may require psychosocial treatment. The important point is that these traits are to a large degree independent of the state disorder at the clinical level. Schizophrenia might be conceptualized as having two components: a trait disorder with chronic disturbance of thought, mood, and social functioning, on which are superimposed recurrent state disorders marked by schizophreniform psychotic episodes. Antipsychotic medications are more useful in the acute and prophylactic treatment of the psychotic episodes than in the treatment of the schizophrenic traits (5, 6, 13, 22). Recognition of the many patients who have one or more schizophreniform psychotic episodes with otherwise normal functioning emphasizes the relative independence of the schizophreniform psychotic state from the schizophrenic character traits (2, 23, 24). Others have tried to make this same distinction by dividing schizophrenia into reactive and process types (23). The definitions of schizophrenia and mood disorder in our schema are rooted in those of Kraepelin, who contrasted the chronicity of schizophrenia (25) with the episodic nature of manic-depressive illness (26).

The use of this conceptual schema might clarify certain issues concerning the proper use of psychotropic medications. One way to conceptualize the role of psychotropic medications is to say that their primary value is in the treatment and prophylaxis of state disorders. In cases in which it is difficult on clinical grounds alone to determine whether a state disorder is present, a therapeutic drug trial can be helpful. It is often useful for future treatment to define a state disorder retrospectively as a disorder characterized by lack of response to psychosocial methods but responsive to a certain drug regimen. The best that can be expected from the pharmacological treatment of a state disorder is a return to baseline (premorbid) functioning. Thus it is crucial to know a patient well and to know his or her baseline in order to assess accurately both the need for medication and the therapeutic end point. The use of medication as prophylaxis against the recurrence of future episodes of a state disorder should be distinguished from the treatment of a particular episode (20, 27). It is during this medication maintenance phase of the treatment of patients with state disorders that psychotherapeutic work, if needed, can be pursued. The importance of a therapist's psychosocial skills in the proper use of medication, including securing patient compliance, should not be ignored.

DISCUSSION

Although for conceptual purposes we have emphasized the independence of state and trait disorders, these processes may in certain ways be related. For example, it is conceivable that the same biological process responsible for manic psychosis also functions in an "organizational" fashion in the development of the personality of the individual with manic-depressive illness. Questions related to the underlying processes in the determination of state and trait components of clinical syndromes await further research. In addition, character traits may color the expression of a state disorder and can affect a patient's ability to cope with and cooperate in the treatment of a recurrent state disorder, such as manic-depressive illness or temporal lobe epilepsy. On the other hand, repeated episodes and hospitalization for these and other recurrent state disorders can affect character traits such as self-confidence and social skills.

There are certain psychiatric disturbances that do not fit well into the schema presented here. There are state disorders that do not respond to current somatic treatment, such as drug-resistant psychosis in schizophrenia (28). Certain trait disorders, such as antisocial character disorder (29), respond relatively poorly to current psychosocial treatment. Minimal brain dysfunction is an atypical disorder in that it has certain trait characteristics but often responds to stimulant medication (30). There are other disorders that we have not attempted to integrate into our present schema, including sexual dysfunction, psychophysiological disorders, alcohol and drug abuse, and chronic organic brain syndrome. However, we feel that the state-trait distinction as presented here may be useful in the analysis of these problems.

In conclusion, we have conceptualized major psychiatric illness as having at least two major independent components that usually require treatment by different methods. The ideas in our schema are consistent with the practices of many contemporary psychiatrists who use pharmacotherapy and psychosocial therapies for generically distinct clinical problems (6). The precision gained by using this schema is helpful in establishing the proper indications for and timing of pharmacological and psychosocial therapies.

Suicide Among U.S. Women Physicians, 1967–1972

BY FERRIS N. PITTS, JR., M.D., ARTHUR B. SCHULLER, M.D., CHARLES L. RICH, M.D., AND ANDREW F. PITTS

The authors examined AMA records of the deaths of 751 women physicians during 1967–1972. Forty-nine (6.56%) committed suicide. The suicide rate for women physicians (40.7 per 100,000 per year) was higher than for men physicians and about four times that for white American women of the same age. From the known morbid risk for suicide among women with primary affective disorder, the authors calculated that about 65% of American women physicians have primary affective disorder.

CRAIG AND PITTS (1) analyzed suicide among physicians by examining the records of 8,372 consecutive physician deaths ascertained by the AMA during 1965-1967. To our knowledge, that was the first time the greatly higher suicide rate of women physicians was recognized and reported.

In the Craig and Pitts study the numbers of women physicians who committed suicide were so small (base population 21,000, 297 deaths, 17 definite suicides) that we conducted a second study to see if the high rate of suicide is constant or variable. We examined all AMA records of deaths of women physicians for the 5-year period 1967–1972. As this report illustrates, the rate of suicide for women physicians continued to be high and nearly constant from year to year throughout this five-year period.

METHOD

The comments on and description of AMA physicians' records and *JAMA* death notices by Craig and Pitts (1) still apply with one exception: physicians are better known to the AMA now as time runs out on the pre-Flexner Report M.D.s, and many fewer need to be declared dead because of their advanced age and unknown address. In the earlier study 5% of physician deaths were by declaration, but such death declarations have declined to approximately 1%. Thus, essentially all physician deaths (99%) are now known to the AMA. Approximately 5% of physician deaths are still reported to the AMA too late for obituary in *JAMA*; about half of these late reports include cause of death; cause of death is not sought for the other 2.5%. Our current sample includes knowledge of cause of death for more than 95% of physician deaths, rather than 92.5% in the previous sample studied.

Because less than 3% of physicians' deaths are suicides, a greatly increased suicide rate in the 5% of physician deaths not reported in *JAMA* could significantly increase the rate of suicide among physicians. A total absence of suicides in this 5%, on the other hand, would not reduce the suicide rate appreciably.

Analysis of Data on Physician Deaths

We examined the materials collected by the *JAMA* deaths editor to obtain as clear a picture as possible of the cause of death. Differentiating suicide, probable suicide, and possible suicide was particularly important because published *JAMA* obituaries are not always accurate in these matters. *JAMA* publishes the cause of death given on the death certificate if available regardless of other circumstances, and in a number of instances of obvious suicide the attending physician chose a euphemistic cause of death. Thus, "asphyxia" was recorded in place of suicidal hanging, "accidental gunshot" instead of self-inflicted gunshot wound in the head, and "accidental drowning" in place of suicide by drowning. These reports have occasionally been made even when there has been collateral evidence of suicidal intent—a suicide note or circumstantial evidence that the deceased physician took great pains to be isolated for sufficient time to achieve "accidental death."

We reviewed the materials collected by the deaths editor for those physician deaths reported by obituary in *JAMA* between May 22, 1967, and May 30, 1972. We also reviewed all available records on deaths of physicians reported to the AMA too late for *JAMA* obituary during these 5 years. This examination of the original data enabled us to clarify many of the ambiguous or euphemistic causes of death listed in *JAMA* obituaries and to increase the category of definite suicides by 18.5% for all physicians and 20.0% for women physicians.

Received Feb. 22, 1978; revised May 2, 1978; accepted June 19, 1978.

0002-953X/79/06/0694/03/$00.40 © 1979 American Psychiatric Association

Our criteria for "definite suicide" were hierarchical. First, a certification of suicide on the death certificate by the attending physician was automatically counted as suicide. A certification by letter from the deceased physician's personal physician, colleague, or physician relative that the death was a suicide (when there was no death certificate available or the death certificate gave a euphemistic cause) was also automatically counted as a suicide.

In the absence of other information, a written statement from the next-of-kin or executor that the physician had killed himself or herself was sufficient for classification as suicide. There were instances in which there was enough information available that we felt justified in calling the death a definite suicide even though the death certification and medical report indicated otherwise, e.g., when a newspaper article stated that a suicide note was found but the death certificate stated that the death was accidental; there were only 2 such circumstances (4% of suicides tabulated) among the deaths of women physicians.

When none of the above criteria were met but there was sufficient evidence that the deceased physician had been psychiatrically ill and had died under suspicious circumstances, we classified the death as "probable suicide." There were only 4 probable suicides of women physicians (8% of total tabulated), all were extremely likely to have been suicides, and the numbers did not affect any of the statistical differences calculated; therefore the 4 probable suicides were included with the 45 definite suicides.

Probabilities given in this report are based on either the standard error of the difference of means or chi square with Yates correction. Differences at the .02 level of statistical confidence are considered significant.

RESULTS

In the five years between May 22, 1967, and May 30, 1972, the deaths of 16,722 physicians (16,063 male, 659 female) were reported by *JAMA* obituary; 2,008 (1,916 male, 92 female) were reported to the AMA too late for obituary. The total number of deaths ascertained by the AMA during this five-year period, then, was 18,730 (17,979 male and 751 female) and a significant percent (10.7% male, 12.3% female, 10.7% total) never appeared in the *JAMA* obituary columns. Fully 20% of the suicides of women physicians were among those 12.3% not appearing in a *JAMA* obituary.

The crude annual death rate was 1,261 per 100,000 per year (3,596 per year per 285,131) for men and 623 (150 per year per 24,088) for women physicians (on December 31, 1969, the midpoint of this study, there were 24,088 women physicians in the United States and its possessions [2]).

The percentage of these 751 deaths of women physicians due to suicide was 6.52; these 49 suicides gave a crude annual death rate by suicide of 40.7 per 100,000 for the five-year period; the death rate by suicide of white women over age 25 for this same period was 11.4 per 100,000 ($p<.0001$) (3).

In comparison, 543 of 17,979 male physician deaths by suicide gave a percentage of 3.02 and a crude annual death rate of 38.1 per 100,000.

The age at which women physicians committed suicide ranged from 25 to 79. The median was 47 years and the mean was 47.8±2.0 (SEM); clearly, the majority of these premature deaths occurred during what should be years of productive professional life.

Drug overdose is used significantly more frequently by women physicians for committing suicide than by the general U.S. female population matched by age and race (71.1% compared to 45.7%), and there is a corresponding lower frequency of gunshot suicide among women physicians ($p<.001$). This increased tendency to use drugs rather than guns is also seen regularly among male physician suicides.

Five of the 45 women physicians who definitely committed suicide were certified medical specialists (one each in ophthalmology, pathology, pediatrics, preventive medicine, and radiology). Practice preference grouping showed 15 in family practice; 8 in residency training; 5 in internal medicine; 4 each in pediatrics and psychiatry; 3 in pathology; 2 in preventive medicine; and 1 each in anesthesiology, obstetrics and gynecology, ophthalmology, and radiology. Since family practice was a residual category no special meaning can be attached to the apparent clustering; otherwise, the numbers in each category were too small to determine anything other than suicide is a cause of death for some women physicians in all types of practice. Apparently it is not the type of practice but the type of woman that determines whether or not she commits suicide. Of the 8 women in training who committed suicide, 2 each were in psychiatry and internal medicine, and 1 each were in pathology, radiology, pediatrics, and obstetrics-gynecology.

DISCUSSION

The rate of suicide among U.S. women physicians in our study does not differ from that of Craig and Pitts's study (1). In their study, 17 of 297 (5.72%) consecutive deaths of women physicians were definite suicides. In this study, 49 of 751 (6.52%) such deaths were suicides. Such close agreement and the constancy of annual occurrence demonstrate that there is a specific process that results in a suicide rate for women physicians approximately four times that of the general population of U.S. white women over age 25. It is about twice that for divorced women over age 70, the demographic group of women in the general population with the highest known suicide rate.

If this high suicide rate for women physicians is constant, it must, then, be due to a specific process, or more than one process, constantly related. In Robins and associates' study (4) of individuals who committed

suicide, 75% were diagnosed, according to strict criteria, as having either primary affective disorder or alcoholism. The remainder had probable affective disorder or probable alcoholism (as a result of insufficient data for strict diagnostic tests). Therefore, since it appears that nearly all individuals who commit suicide are either primary affectively disordered or alcoholic (4) it is highly likely that women physicians who commit suicide have one or both of these conditions. Pitts and Winokur (5) concluded that suicide is the cause of death in 16% (10% of women, 25% of men) of deaths of persons with primary affective disorder. They also concluded that in those alcoholic individuals who commit suicide, alcoholism is a symptomatic consequence of primary affective disorder. If Pitts and Winokur's conclusions are correct then nearly all suicides can be considered the outcome of primary affective disorders, and a morbid risk figure for primary affective disorder for any population can be calculated from the percentage of deaths due to suicide. Craig and Pitts (1) calculated the morbid risk for primary affective disorder to be 10.6% for male and 57.2% for female physicians. The morbid risk for primary affective disorder in women physicians calculated from our current data is 65.2%: 6.52%, the suicide rate among deaths of women physicians, divided by 10%, the suicide rate among deaths of women diagnosed as having primary affective disorder (1, 5). We predict that structured interview studies of women physicians will show that a very high proportion (nearly two-thirds) have primary affective disorder.

We must conclude that there is (or has been) some association between affective disorder and selection of a medical education and career by U.S. women. The rapidly increasing number of women in U.S. medical schools and medicine (2), consequent to the encouragement of women to apply for admittance, may mean that the morbid risk factor for primary affective disorder in women physicians is also changing. The current larger sample of women medical students may be from a different subpopulation of U.S. women, still intelligent but perhaps less laden with primary affective disorder. Those who undertake surveys of suicide and affective disorder among U.S. women physicians must at least consider the rapidly increasing number of women physicians and the resulting skewed age distribution curve.

Steppacher and Mausner (6) also concluded that women physicians have a higher suicide rate than men physicians. They discussed in detail the reliability and validity of suicide data for various populations and emphasized that women psychologists and women chemists also have higher suicide rates than their male peers. We have been unable to locate any other studies of suicide among women physicians.

Whatever the true reasons for the unexpected high suicide rate among women physicians, it is apparently a genuine finding and of heuristic importance. Systematic studies of women physicians using structured interviews and specific diagnostic criteria, with comparisons to other groups of professional women and to less specially educated women, are needed next—not unsupported speculations about "role strain" or pleas to examine the mental content of the physician who commits suicide.

An Attempt to Objectify the Therapeutic Process: A Working Model

BY LAILA KARME, M.D., PH.D., SELMA COOPERMAN, M.D., AND THOMAS PRESTON, M.D.

On the basis of their observations in daily psychoanalytic work the authors developed five objective criteria for "bad" analytic hours. These criteria involve affect, intellectualization, isolation, lack of feedback, and dissatisfaction. The authors developed a formulation to help them preconsciously recognize the presence of these factors during therapeutic work and found that it was helpful in turning a potentially bad hour into a productive one.

THERE IS A GROWING CONCERN with objectivity in psychoanalysis and psychotherapy, especially in these days of peer review and third-party payment. The work described in this report began with an attempt to define, describe, and research the "stalemated analysis." We chose to concentrate only on neurotic patients and on established analyses. Established analyses were arbitrarily defined as those with a minimum of 100 hours, using standard analytic technique, in which both the working alliance and the transference neurosis were well established. We made these choices to avoid the complex issues involved in the opening phase of the analysis as well as the issue of analyzability. We felt that a reasonable approach would be to begin by studying the analytic material microscopically during limited time periods and by isolating specific aspects. It is not possible to observe everything that occurs in the clinical situation, nor is it desirable to do so for scientific purposes; features or variables that are relevant to the questions at hand must be selected.

In an attempt to clarify the cognitive processes involved in "working through," Horowitz (1) presented material from a single session of psychoanalytically oriented psychotherapy. He presented a method of microanalysis that focused on cognitive maneuvers which gradually led to the patient's conscious experience of initially warded-off ideas and feelings, permitting assimilation and working through. Horowitz concluded, "Minute clarifications, if multiplied, can lead to a theory of the process of change in psychotherapy. In turn, such knowledge would lead to improvement in technique."

We used a series of three to four sessions to establish criteria for a "bad" hour or a group of related hours. We maintained the common usage of describing the hours as bad or good with the ultimate goal of translating this vague and unscientific terminology into more precise, definable concepts. We selected hours we "felt" to be bad, the session immediately preceding such hours, and one or two sessions immediately following such hours. We assumed that frequent repetition of bad hours or very extended periods of them would lead to a lack of progress and, if not corrected, eventually a stalemated analysis.

What one observes in the analytic or therapeutic hour is words, intonations, postures, and gestures. The rest is inferred. Affects are inferred because we can measure or observe only their physiological components. For example, we can observe the patient's tears, but to assume the meaning of such tears is an inference. When asked about the affect accompanying the tears, the patient's answer may be that he or she is sad, happy, frustrated, angry, or regretful or even that he or she doesn't really know.

The therapist, no matter how experienced or neutral, is a *participant*-observer and as such is subject to distortions and countertransference feelings. We therefore attempted to subject the recorded observations of each of the analysts to thorough investigation and analysis. For recording, we selected the commonly used method of process notes taken during the session. This method is more reliable than notes taken after a session due to the obvious increased potential for distortion and omission, and in spite of its limitations it has certain advantages. It allows for recording the therapist's feelings, thoughts, and impressions immediately as they occur, which would not be possible in taped sessions. It is also not time-consuming or cumbersome. However, it would be desirable to use our model on tape-recorded or, preferably, videotaped sessions for the purpose of validation.

After each of the three participants had presented what they felt to be bad hours, we attempted to do the following: 1) achieve consensual validation that the

hour was bad, 2) translate the feeling that the hour was bad into definable concepts in support of this feeling, and 3) search for the common denominators in such hours. Criteria that were not consistently found in most bad hours were rejected.

CRITERIA FOR "BAD" HOURS

After we had evaluated 60 sessions it became apparent that five criteria were consistently present in "bad" hours. Any one of these served as an alerting signal, but at least three produced a "bad" hour. Although we do not claim that these are the only valid criteria for bad hours, this working model proved highly reliable for us.

Affect

According to the criterion of affect the patient either displays no affect or, in spite of the therapeutic work, experiences no change in his or her predominant affect over the series of related hours. Another important manifestation is the lack of resonance, reverberations, or empathy in the therapist to the affect displayed by the patient. Aside from the possibility of countertransference, this probably reflects failure of communication because communication is achieved through the evocative power of language. In other words, for the communication to be truly understood one must evoke similar experiences in the receiver. As Peterfreund (2) stated, "Empathy bridges the gap between word and thing representations."

Intellectualization

Too much intellectualization by the patient or by the therapist or both is another criterion for a bad hour. This is somewhat related to the first criterion, but not completely so. For example, some hours showed affective productions by the patient with resonance in the therapist, but the interpretations were formulated in language that was too intellectualized to produce any emotional impact.

Isolation

The criterion of isolation involves a lack of continuity in the productions from the previous hours and, even more importantly, no carry-through into the following ones.

Feedback

Lack of feedback to the therapist's interpretations is another criterion. By feedback we mean something beyond merely accepting or rejecting the interpretation—for example, the emergence of relevant new or supportive material, error-correction, or finer adjustments (explicit or implicit), alteration of the patient's affect, or expansion of his or her awareness. After all, an interpretation is a tentative hypothesis; without the patient's feedback and freedom to correct, refine, revise, accept, or even reject the therapist's interpretation, the analysis or therapy cannot progress successfully.

Dissatisfaction

The final criterion for a bad hour is dissatisfaction, especially on the therapist's part. Dissatisfaction on the patient's part, although valid at times, did not prove to be one of the common denominators.

EVALUATING THE SESSIONS

Having defined these criteria, we devised a shorthand formulation for evaluating our sessions. We imprinted the following formulation on our minds:

1. Affect—none, no change, or no resonance
2. Intellectualization—patient, therapist, or both
3. Isolation
4. No feedback
5. Dissatisfaction

Our purpose in imprinting these concepts (visualized as a box with the criteria listed) was to ensure that the process of evaluation occurred on a preconscious level during the sessions and did not interfere with the free-floating attention of the therapist.

More bad hours and sessions surrounding bad hours were recorded and presented to test this formulation. As a control we analyzed sessions or series of related sessions that we felt to be "good" hours. We did not find at least three of the above criteria in the "good" hours. In the process of doing all this, an interesting phenomenon occurred. Hours that started as potentially bad hours were readily converted into good ones by correcting what was considered faulty. For example, an hour that proceeded for a while with a mounting sense of dissatisfaction by the therapist led to his or her alertness to the possibility of the presence of some of the criteria described above. If the criteria were discernible, the therapist directed his or her interpretations to the specific problems.

For instance, if the therapist sensed the absence of affect or a lack of feedback he or she became aware of the possibility of a countertransference problem that was then identified and dealt with. Occasionally the correction was not possible during the same hour but was achieved in the following session.

CRITERIA FOR "GOOD" HOURS

We judged the hours to be good by the following criteria: 1) active participation by the patient and the emergence of new illuminating material, 2) a sense of cohesiveness and continuity between the sessions, 3) good emotional expression and some qualitative affective change in the patient with reverberations in the therapist, and 4) a sense of working together and satisfaction. We soon learned to use these criteria as tools for the production of good therapeutic work and for

effectively overcoming either resistance in the patient or countertransference problems in the therapist.

DISCUSSION

This system offers definable criteria and is testable for validity. It helps the therapist to become aware of countertransference issues early. It also prevents the therapist from becoming too active and intellectual or remaining totally passive and nonintervening when it is constructive to define the problem and tackle it actively. Activity does not mean talking a lot. Verbal activity is only one aspect of the therapist's mental activity. This mental activity obviously should go on all the time in an effort to understand the patient's verbal and nonverbal communication and the meaning of the unconscious communication, to define problem areas of resistance in the patient or of countertransference in himself or herself, and then to make timely, appropriate interventions. This system also sheds light on subtle resistance. It is certainly a practical model for psychotherapists who see patients once or twice a week in psychodynamic psychotherapy as well as for psychoanalysts. In addition, this work supports the centrality of affective communication to the therapeutic process.

We feel that this report has potential value in two areas: treatment (analytic or psychodynamic psychotherapy) and teaching and supervision of these treatment modalities. We also hope that other therapists will try this simple model in their own sessions with their patients and help validate (or invalidate) our results.[1] Inclusion of the experience of other therapists would certainly prevent the results from being the unique product of our group. With the notable exception of the work done by Horowitz (1) and Peterfreund (3), there is a paucity in the literature of attempts at objectifying the therapeutic process.

Chlorimipramine Therapy for Obsessive-Compulsive Neurosis

BY JAMBUR ANANTH, M.D., LESLIE SOLYOM, M.D., SHIRLEY BRYNTWICK, AND UMASHANKAR KRISHNAPPA

Twenty patients with a history of treatment-resistant obsessional neurosis underwent a 4-week clinical trial of chlorimipramine. Scores on the Psychiatric Questionnaire for Obsessive Compulsive Neurosis, the Leyton Obsessional Inventory, and 3 self-assessments indicated that although there was no significant change in obsessive ruminations, obsessive rituals, horrific temptations, or pervading doubt, there was a substantial, significant improvement in the obsessive symptom item and severity of obsessions, as well as anxiety, depression, and phobia. Side effects were mild. The authors believe that chlorimipramine is the most promising treatment for obsessive-compulsive neurosis.

SINCE OBSESSIVE-COMPULSIVE neurosis has proven to be treatment-resistant and there is no single widely accepted and effective mode of treatment, there is a need for research to develop a more adequate treatment mode. Open studies have suggested that a beneficial effect has been produced by tricyclics such as imipramine, amitriptyline, desipramine (1), and doxapine (2). It has been claimed that clorimipramine is effective (3, 4) or indeed may be a specific anti-obsessional treatment (5).

We did a four-week uncontrolled exploratory study of chlorimipramine, the subjects of which were 7 men and 13 women selected from inpatient and outpatient facilities on the basis of a diagnosis of obsessive-compulsive neurosis. The patients were aged 23–64 and had a history of treatment-resistant obsessional neurosis over a two-year period; all patients gave informed consent. Diagnoses were confirmed by a clinical interview, psychometric data from the Psychiatric Questionnaire for Obsessive Compulsive Neurosis (Solyom, unpublished) and the Leyton Obsessional Inventory (6). Pregnant women and patients with psychosis, epilepsy, organic brain syndrome, or acute physical illness were excluded.

Received Dec. 3, 1976; revised April 21, 1978; accepted May 18, 1978.

The authors wish to thank Jeanne Gould for her secretarial help.

METHOD

After a one-week wash-out period chlorimipramine was administered on a fixed, changing dosage schedule, 100 mg/day during the first week, 150 mg/day during the second week, 225 mg/day during the third week, and 300 mg/day during the fourth week. The dosage was increased weekly unless side effects occurred or marked improvement in psychopathology was apparent.

Assessment procedures included completion of the Psychiatric Questionnaire for Obsessive Compulsive Neurosis and administration of the Leyton Obsessional Inventory before and at the end of one, two, and four weeks of the clinical trial. Self-assessments, which included the Social Adjustment Scale (7), Maudsley Personality Inventory (8), and the Self-Analysis Form (9), were completed by the patients before and after the clinical trial. A brief physical examination (pulse rate, blood pressure, and weight) and laboratory tests (hemoglobin white cell and differential counts, transaminase estimates, alkaline phosphatase, and urinalysis) were carried out before and after the study.

Eighteen of the 20 patients completed the entire study. Two patients discontinued their medication during the third week: a woman who experienced severe drowsiness and difficulty in micturition and a man who became constipated. Dosage had to be altered for 4 more patients because of side effects: during the second and third weeks of treatment 2 patients experienced hypotension manifesting as distressing dizziness, for which the dosage was reduced to 150 and 100 mg/day; during the last week 1 patient developed severe tremors after three days of 300 mg of the medication, necessitating a reduction in dosage to 225 mg; also during the fourth week, dosage was decreased to 100 mg/day for 1 patient because of nausea, dizziness, dry mouth, and sleepiness. In the case of 3 more patients, dosage was not increased beyond 150 mg/day because of improvement.

RESULTS

The mean scores on the Psychiatric Questionnaire for Obsessive Compulsive Neurosis are shown in table

0002-953X/79/06/0700/02/$00.35 © 1979 American Psychiatric Association

TABLE 1
Effect of Chlorimipramine on Mean Scores on the Psychiatric Questionnaire for Obsessive Compulsive Neurosis

Scale	Predrug	Week 1	Week 2	Week 4
Symptom	102	90	91	78[a]
Severity	302	239[b]	172[c]	133[c]
Depression	117	106	63[b]	64[a]
Anxiety	160	121[b]	76[b]	67[c]
Phobia	76	61	44	32

[a]$p<.05$, one tailed t test, df=19.
[b]$p<.01$.
[c]$p<.001$.

1. Of the 20 patients, 9 had improved scores on the obsessive symptom item, 10 did not change, and 1 deteriorated. There was no significant change in obsessive ruminations, obsessive rituals, horrific temptations, or pervading doubt. The score for severity of obsessions was improved for 19 patients and was unchanged for 1 patient at the end of the fourth week. Fourteen had improved depression scores, 2 were not changed, and 4 had deteriorated by the end of the study. On the anxiety item, 17 patients had improved, 1 did not change, and 2 deteriorated during the study. Thirteen patients had improved scores on the phobia scale and 7 were unchanged at the end of the fourth week.

The total neuroticism score on the Maudsley Personality Inventory decreased from 628 to 494 ($p<.02$), and the extraversion score increased from 349 to 424 (n.s.). The total raw score on the Self-Analysis Form decreased from 835 to 729 ($p<.01$). On the Social Adjustment Scale there was statistically significant improvement in adjustment at work ($p<.01$), leisure activity ($p<.01$), and social adjustment outside the family ($p<.01$).

The Leyton Obsessive Inventory measures five items: total number of obsessive symptoms, patient's resistance to symptoms, symptom interference with the patient's activities, number of obsessive traits, and the Cornell index, which indicates the degree of neurosis. Only 8 of the 20 patients completed the tests before and after the study. The resistance score decreased from 181 to 124 ($p<.01$, t test, df=7), the symptom score decreased from 180 to 140 ($p<.05$), the interference score decreased from 197 to 107 ($p<.01$), and the Cornell index decreased from 176 to 137 ($p<.05$). The change in trait score was not significant.

A total of 137 side effects—44 gastrointestinal, 27 central nervous system, 21 psychiatric, 20 autonomic, 16 extrapyramidal, and 7 others—were recorded during the course of the clinical trial. However, all of them were mild and some were transitory and needed no contra-active measures. Gastrointestinal, autonomic, central nervous system, and psychiatric side effects were all greatest during the first week but gradually dissipated, whereas the extrapyramidal symptoms, feeling high, increased appetite, and weight gain occurred only during the second half of the study.

CONCLUSIONS

In our study we noted a substantial decrease in the severity as well as the number of obsessive symptoms. Anxiety, depression, and phobia also improved significantly. Therefore, whether the improvement was due to primary antiobsessional effect or secondary to amelioration of anxiety or depression is debatable. However, while obsessional severity improved significantly by the end of the first week, significant improvement of depressive symptoms was noted only at the end of the second week. This may be indicative of an antiobsessive effect of the medication. Psychometric findings also specifically reflect the antiobsessive effect of the drug by a significant decrease in the symptom, interference, and resistance scores. Scores on self-ratings concur with the findings on psychometric and psychopathological assessments. Therefore, chlorimipramine appears to be the most promising medication for the treatment of obsessive-compulsive neurosis. We are currently exploring the antiobsessive potential of chlorimipramine in a double-blind comparative trial.

Manic-Depressive Variant Syndrome of Childhood: A Preliminary Report

BY RICHARD E. DAVIS, M.D.

The author describes the specific diagnostic entity of manic-depressive variant syndrome of childhood and outlines the five essential diagnostic criteria (affective storms, family history of significant affective dysfunction, hyperactivity, chronically disturbed personal relationships, and absence of psychotic thought disorder) and the five secondary criteria (sleep disturbances, minimal brain dysfunction, abnormal EEG, enuresis, and neuropathology). In the four cases reported, the children, when properly diagnosed, responded well to lithium therapy. The author points out the need for further study of this syndrome. Precautions about the use of lithium in children under age 12 are crucial, as is the need for continuing psychotherapy for parents and child.

ALTHOUGH FEW in number, there are persistent reports in the literature of children and adolescents with major behavioral disturbances who improve greatly when adequate serum levels of lithium are obtained (1–8). Many of these children have been hyperactive and diagnosed as suffering from minimal brain dysfunction or the hyperkinetic syndrome (8). Yet there seems to be a group of factors setting apart a small but significant subgroup of hyperactive children, most notably their positive behavioral response to lithium carbonate, which several studies indicate is not an effective medication for the child accurately diagnosed as suffering from minimal brain dysfunction (9).

In a recent review of the literature on the use of lithium carbonate in children, Youngerman and Canino (1) noted, "In children and adolescents the published literature seems to suggest that aggressivity per se and hyperactivity per se are insufficient indications for the use of lithium carbonate. However, aggressive or hyperactive patients with a major affective component to their behavior may well warrant a trial of lithium carbonate."

In their recent comprehensive book on hyperactive children, Safer and Allen (10) commented, "In the next 10–20 years, as the HA (hyperactivity) becomes more thoroughly explored, a number of other hyperactive syndromes no doubt will be identified."

I propose that there is an identifiable syndrome suffered by a group of persons between approximately 6 and 16 years of age that is characterized by five primary and one or more of several secondary features. I have labeled this entity "manic-depressive variant syndrome of childhood" because its behavioral manifestations do not resemble manic or depressive episodes, but rather a variant of the manic or depressive symptomatology typical of adult life. For this reason the 1960 proposal by Anthony and Scott (11) that one of the essential criteria for diagnosing childhood manic-depressive illness is an "abnormal psychiatric state similar to the classical description" is not appropriate for the group of children identified here, since they do not display classic adult symptoms of mania or depression. The term "juvenile manic-depressive illness" also seems inappropriate for this group for the same reasons (8, 12).

I propose that these young persons can be distinguished from persons suffering from minimal brain dysfunction without such major affective outbursts and from those with childhood or adolescent schizophrenia, autism, and other neurological, medical, and psychiatric illnesses (see table 1) on the basis of five primary criteria (all are essential) and five secondary criteria (one or more are essential).

PRIMARY CRITERIA

Inclusive Criteria

1. *Affective storms.* An affective storm is defined here as a loss of emotional control of major disruptive force in a person under 16 years of age, the precipitating factor being grossly inadequate to explain the degree of emotional outburst. Such disruptive temper outbursts are more intense than the common emotional lability seen in children properly diagnosed as having minimal brain dysfunction. Such storms are transient, irregular, and occur over hours or minutes, not for weeks or months. They may even reach psychotic magnitude, but they are not accompanied by thought process disintegration between such episodes.

The following are typical quotations from the literature indicating the presence of such unusual destructive emotional outbursts in children who are respon-

up care. He has since been removed from lithium therapy, but is continuing moderate doses of thioridazine. No major outbursts have been reported since lithium was discontinued.

Case 2. B, a 9-year-old boy, had had temper tantrums since age 1. He was disruptive at home, fought with his peers, had violent outbursts of temper over relatively minor frustrations, was having serious behavior problems at school, and had normal thought processes. He was reported to be hyperactive, although he could concentrate well at times. He had had restless sleep for years. The father reported that two uncles were "emotionally ill"; one had shot himself, and both were reported to be alcoholic. The mother had been hospitalized once for depression and felt she had "cyclic" but not incapacitating depression. Previously the family had been in family psychotherapy and the boy in play therapy without major changes.

The boy was hospitalized and after negative findings in examinations for organic illness and renal, thyroid, and nervous system pathology, he was placed on lithium carbonate. Several temper outbursts had occurred during his first 2 weeks of hospitalization, one after a serum lithium level of 1.0 mEq/liter was first obtained. During the subsequent 6 months at home, however, he has had no affective storms, the only such 6-month period since age 1. He is maintained on serum lithium levels of 0.8–1.0 mEq/liter. His parents state that he is "a different boy," and there is a compatible family life for the first time.

Case 3. C, an 11-year-old boy, was seen because of severe recurrent temper tantrums, continuous unhappiness, labile mood, hyperactivity, and loss of emotional control since early childhood. He was a chronic restless sleeper. There was no loss of thought control. There were chronic family and sibling fights, and he had previously been reported to have a learning disability. The father reported a grandfather with a "terrible temper," an alcoholic aunt, and one aunt who had episodes of "being wound up day and night" and going on spending sprees.

Methylphenidate and other medications had been tried previously with minimal results. The boy was evaluated and a visual perceptual learning problem was identified; no organic impairment or illness was identified. He was placed on lithium carbonate and a serum level of 0.8–1.0 mEq/liter was maintained.

The boy's major affective outbursts have decreased markedly in frequency and have not reached the former lifelong levels reported by his parents. After 6 months of lithium treatment his parents noted "a remarkable and persistent improvement" in behavior and management.

Case 4. D, a 12-year-old boy, was evaluated because of unmanageable temper outbursts over relatively minor frustrations and because he was becoming physically abusive to his mother during such episodes. He had no friends, was reported hyperactive at school, and had been placed in a special learning center. His grades were poor, but he was intelligent and without thought process pathology.

The boy was adopted; the biological father was known by the adoption agency and was reported to have a violent temper. No further biological family history was available.

An evaluation for organic illness or impairment was conducted, with negative results. The boy was placed on lithium carbonate. Since maintaining serum levels of 0.8–1.0 mEq/liter, he has had no major outbursts during a 3-month period. He recently received the top student award for his group. His parents reported him "markedly improved."

CONCLUSIONS

In this paper I have described the specific diagnostic entity of manic-depressive variant syndrome of childhood. The term "affective storm" was coined and defined to describe a major symptom of the proposed syndrome. Such a diagnosis can be considered when the five primary criteria are present, as well as one or more of the secondary criteria. In the four cases presented, the children, when properly diagnosed, responded well to adequate serum lithium levels (0.8–1.2 mEq/liter). Although more than one disease entity in children may respond to the use of lithium carbonate, this particular syndrome seems to constitute a specific entity. Severe parent-child conflicts existed in all of the families but were most responsive to psychotherapy after control was established with lithium.

The proposal is a tentative and preliminary one and requires further careful delineation or disproof. Precautions about the use of lithium in children under age 12, warning of possible unknown long-range effects, parental education about lithium dosage and toxicity, and prior approval for its use are crucial, as is continuing counseling or psychotherapy for parents and child.

The Elective Within the Required Psychiatric Clerkship

BY MARTIN D. PLUTZER, M.D.

Two important goals of a successful psychiatric clerkship are to maximize students' responsibility and flexibility and to provide knowledge and skills relevant to their future careers. The author describes an elective program within the required medical school psychiatric clerkship that meets these criteria. On the basis of feedback from both students and staff, the author concludes that the advantages of the elective program to students, patients, faculty, and the department far outweigh the disadvantages.

THERE APPEARS TO BE a consensus that a successful psychiatric clerkship for medical students should maximize student responsibility and autonomy. Another important goal is to help the students learn skills that are relevant to their future needs as nonpsychiatric physicians. Kasuboski and Marshall (1) demonstrated that students are capable of assuming major clinical responsibility. Similarly, Linet (2) reported favorably on active student involvement on an acute inpatient unit. Medical students have also been successfully used as therapists in outpatient clinics (3).

It is difficult to design a program that provides an optimal experience for all. Each student has differing conscious and unconscious motivations, expectations, and "resistances." Choice of specialty, capacity for empathy, and ability to deal with psychological matters comfortably may vary considerably among students. In addition, the availability of clinical opportunities is such that involvement in one area frequently precludes involvement in another; i.e., a student assigned to an inpatient unit may miss an outpatient experience and vice versa. In an attempt to meet the needs of the individual student, a traditional approach still used is to offer electives, usually following the required clerkship. Another approach, which emphasizes flexibility, has been to use track programs. Papernik and associates (4) described a program that gave students a choice of clinical assignments, which resulted in diminution in anxiety and improvement in motivation, attendance, and grades. Having a "dignified adult choice" appeared to be most important to students. This selection procedure was so successful it was subsequently adopted by all clinical clerkships throughout the medical school.

Sabshin (5) stated, "Periods of elective learning tend to be utilized in a superior fashion by most medical students who feel themselves responsible for their own voluntary choice." However, the traditional elective following the clerkship is often used mainly by students who are interested in becoming psychiatrists. For a variety of reasons, including limited time and motivation, the majority of students remain uninvolved, but it is these students, many of whom will become primary care physicians, who might benefit the most. To correct this inherent limitation in the use of electives, we have designed an innovative program of electives within the required clerkship at the Medical College of Pennsylvania.

THE PROGRAM

A 6-week psychiatric clerkship is required of all junior students at the medical college. The basic program involves students assuming varying amounts of responsibility for patient care with intensive experience on an acute medical college hospital ward, a more intermediate-care state hospital ward, or as part of the liaison-consultation team. All students rotate on call for 24-hour periods covering the emergency room and the general hospital. In addition, there are required lectures and predominantly clinical seminars.

Received March 23, 1978; accepted May 18, 1978.

Dr. Plutzer is Assistant Professor of Psychiatry, Medical College of Pennsylvania, 3300 Henry Ave., Philadelphia, Pa. 19129.

This work was supported in part by Alcohol, Drug Abuse and Mental Health Administration training grant 5-PO1-MH-10877-12 from the National Institute of Mental Health.

0002-953X/79/06/0706/03/$00.40 © 1979 American Psychiatric Association

The elective program gives each group of approximately 16 juniors the choice of selecting one or more electives. Some students participate in two electives and others participate in none. Our current electives include working in the general psychiatry clinic, where, under close supervision, the student evaluates and provides supportive therapy or "crisis treatment" as indicated. A second elective is participation in a mother-child group as part of a parent education project to explain child behavior and development to mothers of young children. A third elective is active involvement with the alcoholism team, which includes evaluation and counseling of patients. A final choice is a small group seminar stressing reading, active participation, and sharing of clinical vignettes on such topics as the difficult and noncompliant medical patient. The total time for each elective, including preparation, varies from approximately 2 to 5 hours per week, and each may accommodate from 2 to 8 students. Selection is made on the first day of the rotation during orientation. The students are told that the electives are to help them pursue their own interests and learning within the clerkship and will require extra time and work.

DISCUSSION

Advantages of the Program

Electives meet the needs of the individual student. Students with varying interests and capabilities can place themselves where they feel most comfortable along an active-passive continuum. Even within the elective options there is a gradient from active involvement with patients in clinics to a more observational role in the mother-child group. There is freedom of choice with a resulting sense of autonomy and dignity. In addition, the program is relevant to the student's future specialty choice. A student interested in family practice may choose to improve his or her supportive psychotherapy skills, while a future pediatrician may be more attracted to the mother-child group. Finally, the student planning a nonpsychiatric career who would not normally take a psychiatry elective has an opportunity to do so.

Electives meet the needs of our patients. Our clinic experience suggests that a bright, interested, empathic, and well-supervised medical student therapist can be supportive and therapeutic. Paradoxically, some patients transferred to a more experienced resident following the student's departure may express disappointment at the more limited time available.

Electives meet the needs of individual faculty members. An elective with one or two students may be an ideal way of including part-time faculty in teaching. This may have the added benefit of tapping teaching talents and interests previously undiscovered and under used. Voluntary staff who are reluctant to provide a "service responsibility" by themselves are usually happy to supervise an interested student and see a patient with the student. The elective may also be a means of rejuvenating a less than optimal seminar. We found that a moderately successful required seminar was transformed into a highly successful one by restricting the size of the group and making it elective.

Finally, electives meet the needs of the psychiatry department. There is more efficient use of clinical material for teaching. Areas not realistic for large numbers of students are quite appropriate for a few. For example, a department faculty member doing consultation work outside the hospital may teach 1 or 2 students. Elective opportunities may be easily and flexibly added to the program as they become available.

Disadvantages of the Program

There may be scheduling conflicts in coordinating time spent on electives with required ward assignments, supervisory hours, and seminars. Our policy has been that clinical involvement has priority.

There may be initial faculty resistance to change. One colleague complained when his student's supervisory hour was in conflict with an elective alcohol seminar: "You've got them running around doing too many things. They'd be better off just sticking to their ward."

There may be student disappointment and rivalry because of the limited number of electives available and the small size of each group.

Student Response

Student response to the program has been overwhelmingly positive both to the idea of having electives within the clerkship and to the elective experience itself. There is often such a demand for electives that equitable selection during orientation is difficult. One student commented that the elective gave her a valuable outpatient experience in contrast to her inpatient ward assignment. Another wrote, "This elective is far and away the most interesting, exciting, dynamic, and informative first-hand experience of the rotation." Another student commented, "A very good opportunity to actively do, or at least attempt to do, some initial treatment of the type we are more likely to do in our careers." Reflecting on the burdens of the increased responsibility in the clinical elective, a student wrote, "The feeling of independence was scary. The feeling I am responsible for this patient is very different from other rotations."

CONCLUSIONS

Satisfying the criteria of increased responsibility, relevance, autonomy, and flexibility, our elective program within the required clerkship has proved popular and successful according to feedback from students and staff. The advantages far outweigh the disadvantages. There is overwhelming interest in pursuing elective options despite the extra time and effort they re-

quire. Approximately 75% of each junior student group takes one or more electives, even though only 5% to 10% express an interest in becoming psychiatrists. This response would seem to contradict the long-held popular notion that medical students consider psychiatry unimportant. It suggests that when given a choice of areas seen as relevant to their future careers, students are interested. Two important keys to success are adequate coordination of the program and sufficient supervision for the students. An overall advantage is that such an elective program provides a mechanism of flexibility for students, individual faculty members, and the department. Depending on interests and availability, the range of elective possibilities is vast.

The Community Meeting: A Comparative Study

BY RONALD S. RUBIN, M.D.

In this study of two identical open wards, the author found that in ward 1's highly structured meetings a higher proportion of patients participated, and they distributed their participation in more direct proportion to the relative numbers of each present than in the open meetings on ward 2, where patients directed their participation disproportionately to staff. Staff on both wards disproportionately directed their participation to patients, but less so in the structured meetings. The implications of these observations are discussed in terms of the executive ego deficits of the patients involved and their need for structure in the external milieu in order to compensate for these deficits.

SINCE THE EARLY 1950s and the work of Maxwell Jones (1), the concept of the therapeutic milieu has become increasingly entrenched in institutional thinking and practice. One important element in this concept is the ward or community meeting which, from both the literature and personal experience, appears to be one of the very few common elements in all the rather diverse forms that therapeutic communities can take. In some cases the mere holding of community meetings appears to be seen as synonymous with actually having established a therapeutic community. One need not go to such extreme cases, however, to see how central to the therapeutic community concept the community meeting has become. Wilmer (2), for example, not only considers community meetings a requisite for therapeutic communities but also considers their frequency a measure for evaluating these communities. Vitale (3) reported that Maxwell Jones gave similar weight to the importance of community meetings for his own therapeutic communities, and MacDonald (4) felt that community meetings were so common that it was essential to include such meetings in the design of his control or traditional ward.

Despite their popularity, community meetings have not been widely studied. One important reason has been the absence of any simple and economic way of quantifying what occurs in these meetings. There have been some good descriptive studies, but only a few, such as those of Rapport (5), Roberts (6), Fairweather (7, 8), and Kellam and Chassam (9, 10), have provided the kind of data that would make it possible to compare one kind of meeting with another. In an earlier paper (11), Daniels and Rubin described a method of analysis applicable to any large group that used

simple, objective, replicable measures. In the present study I applied this method of observation to the verbal behavior of both staff and patients in two very different kinds of community meetings.

METHOD

Setting and Subjects

The research was carried out on two identical open wards run by medical school psychiatric faculty and residents in a Veterans Administration hospital. Patients were admitted to either ward by random selection and represented a fairly typical Veterans Administration hospital population (8, 11–14). Most of the patients were in their late 30s, unmarried or divorced, high school graduates, with poor or worsening work histories. There was a wide range of psychiatric disorders; the most common ones were character disorder, alcoholism, and chronic schizophrenia. Patients had spent an average of $2^1/_2$ of the past 10 years in multiple psychiatric hospitalizations.

About one year before this study the staff and patients of ward 1 had established the basic outlines of a comprehensive milieu therapy program that stressed a high degree of patient involvement and responsibility. It was centered on the establishment of a ward-based employment service, a policy committee to suggest general ward aims and codes and specific means of achieving them, and an honors committee to enforce ward behavior codes. These three components were jointly run by staff and patients.

Ward Meetings

On both wards meetings were held in the day room, and all ward staff and patients were expected to attend. Meetings on ward 1 were more frequent; they initially were held 4 times a week but were reduced to 3 times a week halfway through the study because of conflicting time demands of other staff-patient task groups. On ward 2 meetings were held twice a week.

The meetings on ward 1 were quite structured. Attendance and minutes were taken by an elected patient secretary. There was a set agenda with minutes read from the preceding meeting, reports of the various committees, old business, and new business. Both staff and patients had to be recognized by an elected patient chairman before they could speak. The ward meeting was considered to be the focal point of ward life in which all major decisions were proposed, discussed, and voted on, information was shared, functioning of the various task groups was scrutinized, and individual patient (and sometimes staff) behavior was discussed. The meeting also served as an "appeals court" for patients who felt they had been unfairly dealt with by their ward administrator or the honors committee.

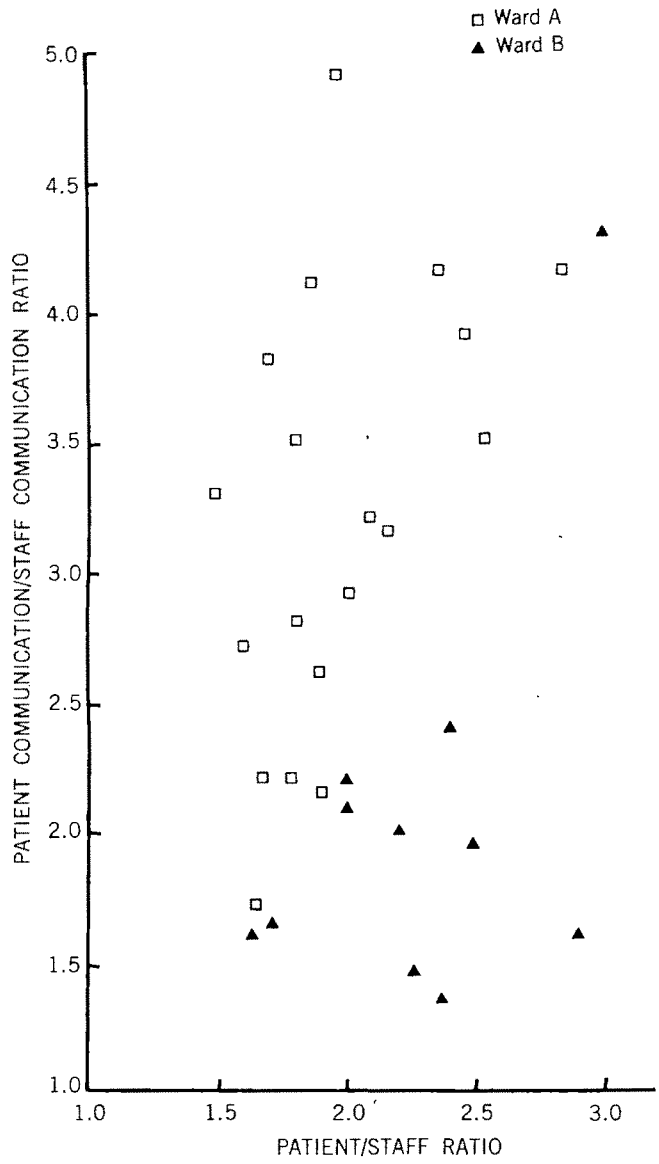
On ward 2 the meetings were much less structured. They were chaired by the chief ward physician, and there was no set agenda, minutes read, or formal attendance. The emphasis was on allowing an open setting in which patients and staff members could raise issues they considered of importance to the ward community.

TABLE 1
Characteristics of Meetings on Ward 1 and Ward 2

Group	Mean Number Attending	Percent Participating	Mean Number of Communications/ Meeting	Meeting Length (minutes) Mean	SD
Ward 1				71.7	24.2
Staff	9.2	69[a]	68.0		
Patients	20.0	62[a]	220.9		
Ward 2				31.5	4.6
Staff	8.9	43	43.3		
Patients	23.7	42	140.2		

[a]Significantly more than on ward 2 ($p=.001$, Student's t test, one-tailed).

Procedure



For 8 weeks a rater attended all community meetings on both wards. Each time a community member made a clearly audible verbal communication his identifying code was recorded, as well as the identifying code of the recipient of the communication (a person, several people, or the community as a whole). A new communication was scored each time the speaker changed the target or the topic of his speech.

RESULTS

The data in table 1 indicate that both meetings were roughly the same size in terms of attendance and proportion of staff to patients (about 1:3). Because of the greater number of patients, their communications predominated in both meetings. Both meetings were quite lively. Meetings on ward 1 were open-ended and lasted 30–168 minutes; meetings on ward 2 were scheduled to last 30 minutes but varied somewhat, with a range of 24–40 minutes. While attendance was roughly the same in both meetings, a significantly higher percent of patients and staff participated in ward 1 meetings (that is, made at least one verbal communication). Thus in the community meetings on ward 1 either there was something going on that elicited a far broader response than in the meetings on ward 2 or there were fewer barriers to participation.

Figure 1 presents information for each meeting, in each ward, on the ratio of the number of patients present divided by the number of staff present versus the ratio of the number of patient communications divided by the number of staff communications. This figure illustrates how verbally active the staff on each ward was as a function of how outnumbered they were by patients. In ward 1 meetings, as the patient/staff ratio increased, so did the ratio of patient communications

FIGURE 1
The Ratio of Staff to Patient Communications as a Function of the Proportion of Each Present

to staff communications as a direct positive linear function. However, for ward 2 meetings there is an almost horizontal line. In other words, no matter how outnumbered they were by patients, the staff on ward 1 did not change their verbal behavior, while on ward 2 the more outnumbered the staff were, the more each staff member talked. Meetings on ward 2 seemed to become increasingly disorganized as the patient/staff ratio increased and the staff felt constrained to intervene more in order to maintain some level of order. Because of the highly structured nature of the community meetings on ward 1, there was not the same tendency toward disorganization and patients and staff were therefore more consistent in their verbal behavior.

TABLE 2
Differential Distribution of Staff and Patient Participation

Direction of Communication	Percent of Staff	Percent of Patients
Ward 1		
To the community	33	26
To staff	12	27
To patients	55	47
Ward 2		
To the community	27	20
To staff	8	40
To patients	65	40

Table 2 presents data on the differential distribution of staff and patient participation, i.e., who talked to whom (to the community as a whole, a staff member, or a patient) and in what proportion. For example, if staff spoke to staff without a bias, the percent of total staff communications directed to other staff members compared with the percent of total staff communications directed to patients would be proportional to the relative number of patients and staff present. On ward 1, with an average of 20 patients to 9.2 staff (from table 1), this ratio should be 2.2:1. On ward 2 with an average of 23.7 patients to 8.9 staff, it should be 2.7:1. The actual ratio of staff/patient communications to staff/staff communications was 4.6:1 on ward 1 and 8.1:1 on ward 2. In other words, staff either differentially avoided speaking to each other or preferentially addressed themselves to patients, depending on how one chooses to look at it. This tendency was significantly more pronounced on ward 2 ($p=.005$, one-tailed Wilcoxon's rank sum test).

The importance of this finding is made clearer when one examines the patient participation pattern. As table 2 illustrates, patients on ward 1 distributed their participation to patients and staff in almost direct proportion to the relative numbers of each present (actual ratio=1.7:1). However, on ward 2, the participation focus appears to have been appropriated by the staff, and patients directed only about one-third of the expected proportion of their communications to other patients (actual ratio=1:1).

CONCLUSIONS

The data clearly demonstrate that participation was less role-stereotyped on ward 1. That is, staff and patients were less differentiated, as groups, by their observed patterns of participation. This was due in part to ward 1's ideology, which stressed concepts such as "democratization" and "egalitarianism," but more importantly to the fact that the structure of the setting facilitated the patients' ability to participate in a fuller and less stereotyped way in the shared life of the ward, i.e., more like "responsible members of the community" and less like "sick patients."

What I am suggesting is that it is not their diagnosed illness that prevents patients from participating in these meetings and causes their participation to be role-stereotyped, but rather the deficits in executive ego function that result from the diagnosed disorder and are often the actual reason the patient is being treated in an inpatient rather than an outpatient setting. I am referring to deficits in the ability to delay gratification, set priorities, tolerate frustration, screen out irrelevant inputs, reality test perceptions, moderate responses, and so forth. Such deficits can be chronic (e.g., severe character disorders, mental retardation, chronic schizophrenia) or transient (e.g., neurotic regressive states, manic or depressive episodes, acute schizophrenia). Finally, such ego deficits can be environmentally exacerbated or minimized. Large group meetings are potentially very disorganizing simply because many people are present and much is going on. In such a setting patients with the kinds of deficits in ego function I am describing will tend to either withdraw or become excited, leading staff to intervene in the first case to "bring the patient out" and in the second to "cool the patient off."

A study such as this clearly raises more questions than it answers. For example, is participation "therapeutic"? Can patients participate vicariously and thus get a great deal out of meetings in which they do not appear to be taking an active part? What about the question of quality as opposed to quantity of participation? Pending final answers, I would like to try to put these issues into some perspective. First, I should say that I do not believe that participation is therapeutic in the way that medication, for example, can be therapeutic, nor even in the somewhat less direct way that psychotherapy can be therapeutic. My working hypothesis is that being engaged in and by his or her human environment is likely to increase a patient's sense of self-worth, and, conversely, failure of engagement is likely to lead to a sense of isolation and futility.

As far as the question of vicarious participation is concerned, in the study mentioned earlier Daniels and Rubin (11) found that active participators did not necessarily feel more positive about community meetings than did less verbally active group members, which does seem to support the idea that patients can be both quiet and engaged. From my findings here I would suspect that the pertinent variable is whether patients can follow the proceedings. I hypothesize that given this population of patients and comparing relatively structured with relatively unstructured meetings, one would find not only a higher proportion of those present participating verbally but also vicariously in the more structured meetings. This hypothesis has the virtue of being relatively easily tested.

Dealing with the quality of participation is not quite so simple. When I initially thought of doing this study I had considered rating participants as to whether they facilitated or inhibited further group processes. A few experiments in this direction eventually convinced me that this was more easily thought of than executed. The problems are related to the subjective nature of the ratings that would have to be made in fast-moving meetings. One solution, of course, is to accept the subjectivity as a necessary aspect of the item being measured and settle for reducing the effect of individual bias by using multiple raters. Unfortunately, videotape is not particularly useful here since there are too many potential participators, which means that raters have to be physically present (although the disruptive effects of this could be minimized by having them behind a one-way screen). My hypothesis is that, given the comparison between less and more structured community meetings and given a population of patients deficient in executive ego function, one would note more evidence of personal disorganization, such as communications that were less lucid and less to the point, in the less structured meetings.

From observations over the past few years, it appears to me that the most common error in running community meetings is the attempt to make them into very large small group therapy sessions. I have not found that large group settings are an appropriate place in which to deal with intrapsychic issues. This often happens by default simply because small group therapy is the only approach to groups for which most of us are formally trained. In saying this, I am not suggesting formal training for community meetings but a more thoughtful approach to what can be usefully done with such a setting. For example, I have already mentioned the importance that I place on the patient's sense of engagement in his or her environment. It seems to me that the community meeting, like the old town meeting that it so much resembles, is an excellent place to establish such a sense of engagement, which I feel most reliably develops when patients have a real say in important decisions affecting their day-to-day lives on the ward, a setting in which they can exercise that say together as a community, and sufficient structure in that setting so that they can participate at their best to make the experience a positive one rather than yet another defeat.

CLINICAL AND RESEARCH REPORTS

This section contains 1) new research findings, including preliminary data from pilot studies, either clinical or laboratory; 2) worthwhile replication studies; 3) case reports that describe a truly new syndrome or cast new light on established ones; and 4) case reports that indicate a new therapeutic procedure of potential value or call attention to adverse effects of drugs or previously unreported complications of therapeutic interventions. Program descriptions and literature reviews cannot be printed in this section. Criteria for format are listed in "Information for Contributors" in each issue; papers that do not adhere to these criteria will be returned to the author.

An Idiot Savant with Unusual Mechanical Ability

BY EDWARD HOFFMAN, PH.D., AND RUSSELL REEVES, SP.A.

The idiot savant phenomenon has continued to be an elusive subject in the fields of psychiatry and mental retardation. In recent years, there have been reports of isolated cases of otherwise typically mentally retarded or autistic persons with unusual abilities in calendar calculation (1, 2) or artistic expression (3, 4). Although there have been various explanations advanced for this condition, most viewpoints are now converging on the hypothesis proposed by Hoffman (2), i.e., that intense motivation, practice, and appropriate reinforcement seem to be necessary if not sufficient conditions for idiot savantism. Recent studies have supported Hoffman's contention that the retarded or autistic individual must have some minimum cognitive functioning, perhaps in the moderate or above range of intelligence, to exhibit the characteristics of the idiot savant.

The purpose of this article is to report a case in which unusual mechanical ability was shown by a moderately to mildly retarded institutionalized man.

Case Report

Mr. A was the oldest of several children born to a rural couple in the 1930s. According to the attending physician's report, the patient weighed 3.4 kg at birth, and the delivery was normal and spontaneous. However, there was no prenatal care and the birth occurred in a rural home that lacked sanitation. The child was bottle-fed, weaned at 18 months, toilet-trained at 30 months, and began to dress himself at 40 months. His home life was described as "meager" by the intake social worker.

Mr. A entered public school at age 5 and left at age 15. He did not learn to read or write and was unable to write his name without a model. He did not speak until age 10. His favorite activity in school was working with machinery. Mr. A's mother died when he was an adolescent. When he was 18, he moved in with an uncle and shortly thereafter contracted a virulent infection that permanently damaged his hearing in both ears.

At that time, he was placed in a state institution by his father, who said he was unable to care adequately for his son. Within weeks after the admission, the father died and a younger sibling became Mr. A's legal guardian. When he was admitted to the institution, Mr. A was found to have a performance IQ of 40 on the Arthur Point Scale of Performance (Form 2), indicating a mental age of 6 years, 5 months. He was diagnosed as having a "cerebral defect, congenital," with no further diagnostic details given.

Mr. A has been institutionalized continuously since the early 1950s. His family visits him less than once a year and remains opposed to his placement in a less restrictive setting. He currently attends a sheltered workshop daily and earns a modest sum for his work. He initiates only minimal social interaction there and at the institution. He wears a hearing aid, but audiometric diagnostic techniques have not fully determined how much of his hearing problem is physical and how much is behavioral. He has not learned to sign, despite repeated attempts over the years.

Current assessment data indicate that Mr. A functions in the mild to moderate range of mental retardation. Testing in 1977 revealed a deaf learning age of 9 years, 4 months, and a corresponding learning quotient of 62 on the Hiskey-Nebraska Test of Learning Aptitude, and a social age of 10.5 years and social quotient of 42 on the Vineland Test of Social Maturity. Periodic intelligence tests over the last 25 years have typically placed his intellectual functioning in the IQ range of 55–65, with far better performance than verbal scores. He can meet all of his self-care needs, tell time, and make change; however, he cannot read, nor can he write anything but his name.

Received Nov. 13, 1978; revised Jan. 19, 1979; accepted Feb. 6, 1979.

Dr. Hoffman is Coordinator, Children's Services, Developmental Disabilities Unit, Massachusetts Mental Health Center, 72–76 Fenwood Rd., Boston, Mass. 02115. Mr. Reeves is a doctoral candidate, Department of Educational Psychology, Wayne State University, Detroit, Mich.

0002-953X/79/06/0713/02/$00.35 © 1979 American Psychiatric Association

Since his admission to residential institutions, Mr. A has received much attention for his unusual mechanical abilities. Previous records note that he typically repaired clocks, electric hot plates, and bicycles of other residents or staff. He was able to disassemble and clean the cottage dishwasher. He ran the film projector and built lamps, requiring only that the appropriate materials and tools be made available to him.

Because of his extreme slowness and deliberateness, standardized tests for mechanical aptitude have proven unreliable and of questionable validity in assessing his abilities. Therefore, a naturalistic experimental assessment was done in 1978 to measure Mr. A's mechanical abilities. In one task, he was given a broken electric alarm clock to repair. Within an hour, he correctly traced the problem to a break in the wiring, at which point he shrugged and handed the clock back to the examiners. In the other task, he was given a 10-speed bicycle that was broken in several places to diagnose and, if possible, repair. Over two consecutive evenings, Mr. A successfully diagnosed all of the problems and indicated by gesture which tools he would need to repair the bicycle.

Mr. A has his own workbench and a set of power tools, and he engages in a variety of mechanical projects in the cottage. He repairs bicycles for other residents, constructs wood-paneled and mirrored coatracks for sale, and spends much time adding mirrors, lighting fixtures, and extra electrical connections to his own stereo equipment, lamps, and bicycle. His most recent project has been to connect the wiring of his stereo set, headphones, and room lamp with one switch beside his bed.

Mr. A tends to be a social isolate in the cottage and devotes almost all of his free time to his mechanical pursuits. He receives much praise and attention from other residents and staff members for his abilities and is certainly aware of his talents. Aside from his mechanical abilities, his behavior is quite typical for institutionalized individuals of his mental capacity.

Discussion

The available information suggests that Mr. A's condition fits the general paradigm advanced by several investigators of the idiot savant phenomenon. First, his intellectual performance lies within the proposed minimum range for idiot savantism (2). It appears increasingly unlikely in view of other case reports (1, 3, 4) that the condition can occur much below this intellectual range, and to date no such cases have been documented to our knowledge.

Second, Mr. A's case history also suggests that his mechanical abilities were strengthened by a great amount of motivation and practice, which began in his school-age years. In his current residential setting, staff members have shown him how to use various power tools, and he has achieved independence with these tools only after careful supervision. As mentioned earlier, he typically spends several hours each evening on his projects, working slowly and methodically. He prefers this self-initiated activity to group entertainment or outings.

Observations in the cottage have also indicated that he receives extensive social reinforcement from staff members, as well as other residents, for his mechanical pursuits. For instance, staff members proudly show even the most casual visitor to the cottage Mr. A's tools, materials, and completed electrical and mechanical projects, which fill his room and part of a nearby lounge area. From his satisfied smiles and low chuckles as he works, it seems clear that he also receives strong self-reinforcement for these mechanical pursuits.

While we are not arguing that the idiot savant condition is due entirely to the influence of external or environmental factors, this case supports the emerging paradigm for the phenomenon. That is, as Hoffman (2) and Morishima and Brown (3, 4) have argued, the necessary if not sufficient conditions associated with idiot savantism appear to be a minimal cognitive level of functioning, intense practice and motivation aided by a funneling of external stimuli, and strong reinforcement to develop and maintain the unusual ability. The other prerequisite seems to involve an idiosyncratic pattern of intellectual performance, evidenced in this case by Mr. A's aptitude and preference for mechanical tasks.

The "Psychotic" Curse

BY ROBERT J. PARY, M.D.

Until recently profane speech from a patient on prolonged neuroleptics might have evoked little added concern. Usually the profanity was assumed to be related to the patient's worsening psychosis. A recent case report by Klawans (1), however, may necessitate clinicians modifying their approach to profanity in a person undergoing chronic neuroleptic treatment. Klawans reported the case of a 28-year-old woman who developed Gilles de la Tourette's syndrome after 6 years of chlorpromazine therapy.

Tourette's syndrome consists of facial and/or body tics associated with either inarticulations or coprolalia (2). Following is a case report of a woman who developed Tourette's syndrome after prolonged neuroleptic therapy.

Case Report

The patient was a 19-year-old woman whom I first examined in 1978, on her seventh psychiatric admission. She had religious delusions, auditory hallucinations, and an extremely flat affect. Physical examination revealed paroxysmal eye blinking associated with either episodic cursing or inarticulations. Grimacing facial features often accompanied the episodic outbursts. There were no signs of oral-buccal or masticatory tardive dyskinesia, nor were there involuntary movements of the extremities. The remainder of the examination was unremarkable.

A chart review revealed that the patient was first admitted in 1972 and had since then been treated with increasingly higher doses of neuroleptics. Beginning in 1977 she was treated with multiple daily neuroleptics. The dosages were equivalent to more than 2000 mg/day of chlorpromazine for 6 months, and for several weeks the dosage was over 4000 mg equivalents of chlorpromazine (3). During 2 of the 6 months of moderately steep neuroleptic dosages, 23 nursing shift notes recorded that the patient had been hissing. A chart review failed to document any serious medical or neurologic illness, nor did the review indicate any observations of facial or body tics before July 1978.

The patient was one of 11 children. Both of her parents and all of her siblings were living, and none showed any evidence of neurological or medical illness. The patient's mother and 1 brother had been hospitalized in the past for auditory hallucinations and persecutory delusions.

The patient was treated with haloperidol in increasing amounts to 100 mg/day. Initially there was little change in her delusions and hallucinations; however, her profanity diminished, although she still exhibited inarticulations associated with paroxysmal eye blinking. The haloperidol was gradually reduced to 20 mg/day due to symptoms of lethargy. EEG, ceruloplasmin, and cerebrospinal fluid, including titers for encephalitic antigens, were normal. On 20 mg/day of haloperidol at discharge, she still manifested minimal eye blinking associated with inarticulations. Her delusions were much less pervasive than when she was first admitted, and her hallucinatory material was greatly reduced.

Discussion

When the patient was first seen in July 1978 the cursing and facial tics received little extra attention. It was assumed that the tics were idiosyncratic mannerisms of her schizophrenic process. Ascher (4) remarked on the similarity of certain signs of Gilles de la Tourette's syndrome to those observed in schizophrenia; his statements took on new meaning as the frequency of the patient's tics and profanity decreased with increasing haloperidol, even though her delusional thinking and hallucinatory material remained unchanged. The response seemed quite similar to the response of early tardive dyskinesia to neuroleptics. In fact, a classification of complex dyskinesias by Crane (5) encompasses both paroxysmal eye blinking and respiratory dyskinesias, which may cause peculiar vocalizations or grunts.

It is possible that tardive dyskinesia could be manifested by a complex dyskinesia initially without signs of the more common oral-buccal or extremity dyskinesia. Stevens (6) presented a study showing that paroxysmal eye blinking may be the initial sign of tardive dyskinesia in the absence of oral-buccal or other dyskinesia.

A neuroleptic-induced Tourette's syndrome is compatible with the present knowledge about dopamine. Snyder (7) postulated that Tourette's syndrome is related to a dopamine receptor hypersensitivity. Tardive dyskinesia is also thought to be related to a dopamine receptor hypersensitivity after chronic, neuroleptic-induced dopamine receptor blockade (8). Klawans (1) discussed the possibility that rebound neuroleptic-induced dopamine hypersensitivity may be manifested as Gilles de la Tourette's syndrome.

To include Gilles de la Tourette's syndrome among the possible presentations of tardive dyskinesia may have pertinent clinical applications. Profanity or inarticulations in patients receiving chronic neuroleptic treatment will necessitate greater scrutiny. No longer can these signs be rubberstamped as part of the patient's psychosis unless the clinician also observes for muscular tics and considers the possibility that the profanity was induced by neuroleptics.

Anxiety and Serum Prolactin

BY ROY J. MATHEW, M.D., BENG T. HO, PH.D., PATRICIA KRALIK, M.S., AND JAMES L. CLAGHORN, M.D.

The recent development of reliable radioimmunoassay methods for measuring serum prolactin has led to studies that indicate this hormone may respond rapidly and markedly to psychological influences in both man and animals. It is well established that stress can elevate prolactin in animals (1, 2) and a similar relationship has also been demonstrated in humans (3). However, the precise relationship between prolactin release and stress-related psychological areas such as anxiety is unclear (4).

The aim of the present study was to investigate the effect of anxiety and relaxation on serum prolactin in a group of subjects with chronic anxiety. A nonpharmacologic form of treatment was chosen to eliminate the confounding influence of psychotropic agents (5). Because hormone levels are influenced by several factors (sex, exercise, etc.), the patients were used as their own controls (5).

Method

The subjects were 11 outpatients (8 women and 3 men) aged 26 to 55 years who had generalized anxiety disorder according to Research Diagnostic Criteria (6). Patients with a history of alcoholism or drug abuse were excluded. All subjects, including those who were taking psychotropic medication at the time of screening, were required to undergo a minimum washout period of 1 week. A thorough physical examination and routine laboratory tests, including assays for stress-related hormones, T3, T4, and T7, were done to rule out concomitant physical illnesses. The patients were given firm instructions to avoid all forms of medication during their participation in the study. Pertinent background data were recorded during the second visit. Subjects were then requested to lie down and relax alone for 30 minutes in a quiet, semi-dark room. The first blood sample for prolactin assay was drawn immediately after the relaxation session. Blood was collected between 11 a.m. and 12 noon, when the endogenous prolactin levels were shown to be at their minimum. Subjects then filled out the State-Trait Anxiety Inventory (STAI).

The State-Trait Anxiety Inventory is composed of separate self-report scales for measuring two distinct types of anxiety. State anxiety is conceptualized as a transitory emotional state or condition characterized by 1) subjective, consciously perceived feelings of tension and apprehension, and 2) heightened autonomic nervous system activity. Trait anxiety refers to individual differences in tendencies to respond to situations perceived as threatening with increased state anxiety (7).

During the next 3–4 weeks the subjects received nine 30–40 minute relaxation training sessions. Four subjects received Jacobson's progressive relaxation training (8) and were given biofeedback-assisted relaxation training. The subjects were instructed to practice the relaxation exercises at home for 20 minutes a day. After the training was completed the subjects returned to the laboratory for final evaluation. The STAI was administered and a second blood sample drawn after the subjects relaxed in a quiet, semi-dark room for 30 minutes.

Serum was separated from 6–8 ml of venous blood within 2–3 hours after collection. Prolactin was determined by radioimmunoassay using a commercial reagent kit modified for liquid scintillation spectrometry and for increased sensitivity (method of Kralik and Ho, unpublished).

Results

The pre- and posttreatment STAI scores and prolactin levels were compared using paired t tests. There were significant reductions in both state anxiety ($t=3.16$, $p<.01$) and trait anxiety ($t=3.56$; $p<.005$).

The change in serum prolactin level following treatment was insignificant and inconsistent (13.74 ng/ml±6.93 versus 13.12±7.40). Pearson product moment correlations showed no significant pre- or post-treatment relationships between serum prolactin and either state or trait anxiety.

Discussion

Although there were significant reductions in anxiety following relaxation therapy, no consistent correlations could be found between the prolactin and anxiety levels before and after treatment.

Stress has been shown to increase prolactin secretion (3). However, stress does not always cause anxiety and has been shown to induce more than one response (9). Our inability to find a relationship between serum prolactin and chronic anxiety and anxiety relief does not necessarily argue against a link between stress and this hormone.

It is important to note that the lack of a prolactin-anxiety relationship applies only in chronic anxiety. Since it has been established that endocrinologic changes seen in association with acute stress are different than those seen with chronic stress (10), it is likely that the endocrinology of acute anxiety is different from that of chronic anxiety.

Haloperidol, Hyperthyroidism, and Sudden Death

BY MYRON F. WEINER, M.D.

Death due to aspiration asphyxia in patients treated with phenothiazines has been reported many times. The mechanisms postulated are regurgitation due to loss of control of esophageal sphincters and impairment of swallowing (1, 2). Moore and Book (3) cited a report of absent gag reflex in 40.3% of psychiatric inpatients treated with phenothiazines compared with 9% of controls. Solomon (4) reported on a patient treated with fluphenazine who had absent gag reflex and a bulbar palsy-like syndrome; he postulated that aspiration might result from the patient's inability to close the glottis or to create sufficient intrathoracic pressure to cough (4).

This case is to our knowledge the first report of death due to aspiration asphyxia in a patient treated with haloperidol, a nonphenothiazine antipsychotic drug.

Received Dec. 20, 1978; accepted Feb. 5, 1979.

Case Report

Ms. A, a 43-year-old woman, was admitted to a psychiatric inpatient service because of bizarre behavior noted by her husband and family. She had become preoccupied with photographs of her dead son, talked as if he were alive, slept little, and was agitated and hostile. She was brought to the hospital when she expressed the feeling that people were trying to kill her.

On admission, Ms. A was confused, agitated, and talked almost continuously. She was oriented to place and person but thought the year was 1955. Her recall and recent memory were intact. She expressed ideas of reference and of extern control.

Her medical history (obtained after admission) incl treatment for pulmonary tuberculosis in 1965, hyster pingectomy in 1969, and heavy alcohol intake up years before admission. Ms. A had lost 22.7 kg in years before admission and had noted increased hai dry skin for about 4 years.

On admission, Ms. A's blood pressure was 12 piration was normal, and her pulse was 144, w lar beat heard. She had pharyngeal exudatio and questionable muscle weakness and wa

Ms. A was placed on haloperidol, 5–25

0002-953X/79/06/0717/02/$00.35 © 1979 American Psychiatric Association

tropine mesylate, 2 mg/day. By the 3rd hospital day she was still agitated but expressed no delusions, and her pressure of speech had diminished. On the 7th day she complained of sleepiness and difficulty breathing due to nasal stuffiness. Examination revealed a reddened pharynx with whitish exudate. Her respiratory rate was 25 and her apical pulse was 180 and slightly irregular.

On the 8th day a throat culture was reported to be negative. Ms. A complained of difficulty breathing due to nasal stuffiness but was "unwilling" to open her mouth to breathe. She had mild paucity of movement and was agitated and diaphoretic. Her blood pressure was 142/92, respirations were 28, and pulse 196.

On the 9th hospital day thyroid studies revealed T_3 uptake greater than 75% and T_4 of 24.9 μg/100 ml. An ECG showed atrial fibrillation. The thyroid was not markedly enlarged to palpation. She was transferred to the internal medicine service and was started on digoxin, 0.25 mg/day, propanolol, 160 mg/day, and phenobarbital, 60 mg b.i.d. Haloperidol and benztropine mesylate were discontinued.

On the 13th hospital day Ms. A refused to undergo a thyroid scan, stating that the orderly had come to take her to the morgue. Later in the day, after a nurse convinced her to have the scan, she fled from the nuclear medicine department after asking if the people dressed in street clothes (outpatients) had come to pick up deceased relatives. She was restarted on haloperidol, 10–15 mg/day, in addition to her other medications. She underwent a thyroid scan on the 15th day that showed 50% uptake and gland size 2–3 times normal. Thyroid antibodies were reported negative on the same day.

On the 16th hospital day Ms. A received a therapeutic dose of ^{131}I. At that time, she complained of increased salivation. On the 17th day nursing staff noted that she was constantly salivating and tremulous. She was anxious and demanding of attention on the 19th day. Her oropharynx was suctioned twice in the morning. She complained of difficulty in swallowing fluids and solid foods. At 4 p.m., her blood pressure was 190/100, pulse 130 and irregular, temperature 99°F, and she was restless. At 4:10 p.m., she had some ice cream and some orange juice; a little later she drank half an ounce of milk. Shortly after 7 p.m., Ms. A was found without respiration, with fixed pupils, and no detectable pulse. Creamy liquid was suctioned from the endotracheal tube that was inserted. Cardiopulmonary resuscitation was unsuccessful and the patient was pronounced dead at 8:28 p.m. An autopsy was not performed.

Discussion

Several reports in the literature indicate that hyperthyroidism enhances the neurotoxic effects of haloperidol.

Lake and Fann (5) reported a case in which there was a clear relationship of the hyperthyroid state to extrapyramidal side effects. Their patient developed tremor, muscle fasciculations, and pronounced rigidity. When he was taken off haloperidol and treated to a euthyroid state with propylthiouracil (PTU), his rigidity abated. After PTU was discontinued, he was restarted on haloperidol, 8 mg/day, for his psychotic behavior, and did well for 15 days. Two days after treatment with ^{131}I his hyperthyroid state returned, despite resumption of 600–800 mg/day of PTU, and was accompanied by a recrudescence of parkinson-like rigidity. Haloperidol was discontinued 5 days after radiotherapy and propanolol was started to reduce tachycardia. After clinical and laboratory evaluation indicated he was euthyroid, the patient was able to tolerate haloperidol, 8 mg/day, for another 45 days in the hospital without unusual reaction.

Yosselson and Kaplan (6) reported on a patient who had uncontrolled hyperthyroidism and had taken haloperidol, 4 mg/day, and who then developed severe weakness, inability to speak or walk, facial rigidity, and dryness of the lips and tongue.

Hamadah and Teggin (7) described a 74-year-old woman with unsuspected hyperthyroidism who developed boardlike rigidity, dyspnea, cyanosis, and inability to swallow fluids after taking haloperidol, 6 mg/day for 20 days.

Flaherty and Lahmeyer (8) suggested that a laryngeal-pharyngeal dystonia was the cause of respiratory distress seen in two presumably euthyroid patients treated with haloperidol. An absent gag reflex was noted in one patient. Both patients responded well to intravenous diphenhydramine and temporary maintenance on 2 mg/day of benztropine mesylate.

The patient we have described developed a bulbar palsy-like syndrome with difficulty swallowing, probably in connection with an exacerbation of her hyperthyroid state after a therapeutic dose of ^{131}I, as occurred with the patient described by Lake and Fann.

The increased risk of dystonic reactions suggests that haloperidol should be routinely accompanied by antiparkinsonian agents or that less potent dopamine blockers should be employed in treating psychotic hyperthyroid patients. The development of a severe extrapyramidal reaction to haloperidol may also suggest undiagnosed hyperthyroidism.

Potentiation of Lithium by Tryptophan in a Patient with Bipolar Illness

BY GUY CHOUINARD, M.D., M.SC.(PHARMACOL.), BARRY D. JONES, M.D., SIMON N. YOUNG, PH.D., AND LAWRENCE ANNABLE, DIP.STAT.

The results of our recent double-blind controlled study of the action of tryptophan and imipramine in the treatment of newly admitted depressed patients led us to hypothesize that unipolar and bipolar patients differ in their response to tryptophan (1, 2). Bipolar patients and patients with acute mania seem to require higher doses of tryptophan than do unipolar patients. Two studies of acute manic patients showed moderate (3) or no (4) therapeutic effect with 6 g of tryptophan a day, but a third study achieved better results using an average dose of 9.6 g/day (5). In an unpublished pilot study we have obtained encouraging results from the use of 12 g/day of tryptophan in manic patients. If high doses of tryptophan are therapeutic in both manic and bipolar depressed patients, this drug might be useful in manic-depressive illness, especially for patients who do not respond satisfactorily to lithium. This paper is, to our knowledge, the first report of potentiation of lithium by tryptophan in a patient who responded poorly to lithium.

Case Report

Ms. A, a 46-year-old married woman, had no psychiatric history and was working successfully in an executive position when she experienced her first depressive episode at age 42. The episode was characterized by lack of energy, suicidal ideation, insomnia, weight loss, guilt feelings, and feelings of helplessness. These symptoms responded to amitriptyline, 50 mg p.o. b.i.d., but Ms. A stopped the medication because she became overactive and hostile, exhibited pressure of speech, and began spending inappropriate sums of money. Approximately 1 month after she stopped taking the antidepressant, she became extremely depressed and was admitted to the hospital with suicidal ideation. In the hospital she responded well to tricyclic antidepressants and was discharged, but 6 weeks later her hypomanic symptoms reappeared. Although the medication was continued, her depressive symptoms returned within 1 month and she was readmitted after she attempted suicide by overdose. She was given antidepressants, recovered, and was discharged.

At this point, Ms. A started a cyclic pattern of mood changes that usually consisted of a 2-week period of mania or hypomania, 2–3 days of normal mood, and then 2 weeks of depression (the depressed phase lasted up to 2 months at times). This cycle did not correspond to her menstrual cycle. During the depressed phase Ms. A was unable to do anything beyond the most basic necessities of caring for herself, and she spent most of her time in bed. It was necessary to discontinue antidepressants because they precipitated more severe manic periods and did not prevent the depressed phase.

At the age of 44, Ms. A was readmitted to the hospital in an attempt to stabilize her on lithium. Lithium carbonate, 300 mg p.o. q.i.d., lessened the severity of the manic phase, but the time course of the cycle remained unchanged. Approximately 3 months after she was discharged, perphenazine, 4 mg/day, was added to lessen the subjective anxiety that she experienced during both depressed and manic phases. Throughout the next year and a half, Ms. A continued to experience the cycle of depressive and manic periods and was unable to work despite serum lithium levels of approximately 1 mEq/liter. She lived with friends who cared for her during the recurrent depressed phases and prevented her from acting on her severe suicidal ideation.

Ms. A was referred to our pharmacology research unit for consultation concerning possible change in the treatment regimen, which consisted then of lithium carbonate, 300 mg p.o. q.i.d.; perphenazine, 4 mg/day p.o.; and flurazepam, 30 mg q.h.s. as needed for insomnia. Her medical history included a male first cousin on her father's side who had a history of bipolar affective illness. Physical examination and routine laboratory analysis were normal. There was no history of drug abuse or alcoholism.

It was decided to add L-tryptophan, 3 g p.o. b.i.d., and nicotinamide, 750 mg p.o. b.i.d., to her treatment regimen. Informed written consent was obtained from the patient. Nicotinamide was given with tryptophan in order to decrease the peripheral catabolism of tryptophan by tryptophan pyrrolase (6). She was rated on the Hamilton Rating Scale for Depression, the Beck Self-Rating Inventory for Depression, and a 5-item mania scale before treatment and at weekly intervals thereafter. At the same time intervals, blood was drawn for the measurement of plasma tryptophan and serum lithium. An ultrafiltrate of plasma, prepared as described previously (2), was used for the measurement of free (non-albumin-bound) plasma tryptophan. Tryptophan was measured by the method of Denckla and Dewey (7). On day 30 of the trial, the dosage was increased to 3 g q.i.d. of L-tryptophan and 1 g q.i.d. of nicotinamide. She tolerated this high dose very well. During the 8th week she discontinued flurazepam because her sleep had improved and at week 10 a marked reduction in anxiety enabled her to stop the perphenazine. She continued throughout the trial on lithium carbonate, 300 mg p.o. q.i.d.

Table 1 shows the results of all evaluations. It can be seen that during the study period Ms. A exhibited 2 complete cycles, the first ending on week 3 and the second ending on week 8. The depressed phase of cycle 2 was reduced in intensity on both the Beck and Hamilton scales as compared with the first cycle. The third cycle started on week 9 with a manic phase of slightly reduced intensity, but on week 10, when the patient's plasma tryptophan levels were higher than any level reached previously, she was considered by

both herself and two psychiatrists to be normal. At the time of writing she has remained normal for sixteen weeks. The only item on both the Beck and Hamilton scales that remains elevated is sexual dysfunction, consisting of a loss of libido. The patient has not yet resumed her normal sex life.

Discussion

Although lithium is usually an efficacious treatment for bipolar affective illness, there remains a small percentage of patients who do not respond satisfactorily. Incomplete responders to lithium therapy are often given additional medications such as neuroleptics or tricyclic antidepressants, but such drug combinations have met with little success. In the case described here, the patient had been treated with tricyclics, lithium alone, and subsequently with lithium in combination with a neuroleptic. These treatment regimens had not adequately controlled her manic or depressive symptoms or altered the cycle's length. However, the addition of tryptophan-nicotinamide to lithium resulted in an almost complete remission of symptoms. The first effect was seen 7 weeks after addition of tryptophan-nicotinamide, with a reduction in the severity of the depressed phase. After 10 weeks the patient entered her first extended period of normality since the illness began 4 years ago.

Lithium reduced the severity of both manic and depressed episodes, but the cycle itself continued. The addition of tryptophan-nicotinamide resulted in a further reduction in the severity of symptoms and a return to normality. However, we have clinical and biochemical evidence from studies in progress which indicates that the cycle continues but does not induce symptoms in the patient. For example, Ms. A reports greater difficulty in sleeping at the time of the expected switchover. This suggests that tryptophan acts in a similar way to lithium and raises the question of whether tryptophan potentiates the action of lithium or has a therapeutic effect of its own. Whatever tryptophan's mode of action, this case is consistent with our hypothesis (1, 2) that only high doses of tryptophan are of therapeutic value in bipolar illness, whereas lower doses are required in unipolar illness. The fact that tryptophan may have some antimanic action in acute mania when given at high doses (unpublished data) also supports the idea that tryptophan when given in combination with lithium may be an effective and nontoxic prophylactic agent for use in manic-depressive illness.

Binge Eating Associated with Oral Contraceptives

BY RICHARD A. MOSKOVITZ, M.D., AND AURORA LINGAO, M.D.

Binge eating has been described recently (1–4) as a distinct clinical syndrome with possible neurophysiologic correlates. It is characterized by sudden, uncontrollable episodes of excessive eating, usually ending in physical distress. It may be followed by self-induced vomiting and usually leads to feelings of remorse or self-contempt. Although similar behavior occurs in some patients with anorexia nervosa, the relationship of the binge-eating syndrome to anorexia nervosa is unclear (5).

The following case, a typical example of this syndrome, was marked by a dramatic remission of symptoms following discontinuation of an oral contraceptive. It is to our knowledge the first reported case correlating clinical change in symptoms with changes in the EEG.

Case Report

A 25-year-old single woman was referred for compulsive eating of 3 years' duration. Since age 21 she had experienced abrupt episodic eating binges characterized by a driven, ego-alien feeling. She could identify no precipitating circumstances or emotions. The episodes lasted from 15 minutes to several hours and occurred in clusters over 2 to 5 days. The clusters were spaced from several days to several weeks apart, alternating with periods of strict dieting. She was 152.4 cm tall and maintained her weight at 47.7–48.6 kg despite acute fluctuations of 1.8–2.3 kg during binges.

The binges generally occurred in solitude and secrecy. They tended to occur in the evening but could occur at any time of day. The patient would rapidly consume large amounts of food, mostly sweets and starches but also leftovers and other ready-to-eat fare. Each episode would end with marked abdominal distress or sometimes sleep but no vomiting. After each binge, she felt helpless, disgusted, and guilty. Depression accompanied each cluster of binge eating, with insomnia, feelings of defectiveness, and fear of losing control. The frequency and intensity of the binges fluctuated. She could recall no binge-free interval longer than 1 month since the onset of the episodes.

Aside from infrequent headaches, which were rarely severe, she had no other major psychiatric or neurologic symptoms. The patient appeared to function normally in other respects. The only remarkable aspect of her medical history was the use of oral contraceptives continually since age 19. She had taken one combination pill for about 2 years and changed to another, which contained 1 mg of norethindrone and .05 mg of mestranol, when she was 21.

Neurologic examination was unremarkable. Thyroid studies and a glucose tolerance test done before referral were normal. Her initial EEG was remarkable for bifrontal, rhythmic slow and sharp activity. A follow-up EEG 1 month later was similarly abnormal. A CT scan showed left-sided punctate basal ganglia calcification of undetermined significance.

After 8 months of further evaluation and psychotherapy, the patient accepted our recommendation to discontinue her birth control pills on a trial basis and was fitted with an IUD. She reported a gradual improvement in her symptoms over the next 2½ months. By the end of this time she noted a marked change, with only 1 episode of overeating during the following 3 months. This episode, on Thanksgiving, was not accompanied by the usual drivenness and emotional sequelae. Her mood and self-esteem improved with the abatement of symptoms, and her weight stabilized at 45.4 kg. A follow-up EEG 5 months after she stopped taking the oral contraceptive showed marked reduction of epileptiform activity and was only marginally abnormal.

Comment

Several reports (1–4, 6) have linked binge eating with abnormal EEGs. The significance of small sharp spikes and 14- and 6-per-second positive spikes, which account for the majority of these abnormalities, has been debated. Two groups of researchers (1, 3) have reported encouraging results from treating binge eaters with phenytoin. Rau and Green (4) have reported a correlation between an inventory of soft neurologic signs, including EEG abnormalities, and clinical response to phenytoin.

Hypothalamic dysfunction has been suggested (1–3) as a possible etiology for the binge-eating syndrome. Either an inhibitory effect on the ventromedial satiety center or an excitatory effect on the lateral appetitive center of the hypothalamus could lead to hyperphagic behavior.

Since oral contraceptives exert at least part of their effect at the hypothalamic level (7), they might influence the emergence of binge eating. The almost exclusive occurrence of this syndrome in females, primarily of child-bearing age, further suggests a hormonal effect, although psychodynamic explanations have also been offered (5). These considerations led us to request that our patient stop her medication.

We postulate that the marked improvement in our patient's symptoms and the associated improvement in her EEG resulted directly from her discontinuing the use of birth control pills. These assumptions are limited by our omission of blind technique and our failure to rechallenge the patient with her medication. Nevertheless, the subacute time course of her im-

provement suggests that this was not a placebo effect.

This case provides further evidence to support a neurophysiologic mechanism for the binge-eating syndrome. It particularly suggests a role for disordered hypothalamic function. Since our patient's symptoms were correlated with an epileptiform EEG pattern, we further suggest that her symptoms resulted from overexcitability of the lateral hypothalamus.

The epidemiology of binge eating raises the question of its frequency of association with oral contraceptive use. While none of the authors cited above indicate which of their patients were using these drugs, we would expect, according to chance alone, that some were. It would be interesting to see whether reanalysis of their data shows correlations between oral contraceptive use and either EEG abnormalities or positive response to phenytoin.

CT Scan Variants and Genetic Heterogeneity in Schizophrenia

BY ROBBIE CAMPBELL, M.D., PETER HAYS, M.B., DON B. RUSSELL, M.D., AND DAVID J. ZACKS, M.B.

Although it is well known that genetic factors are important in the etiology of functional psychoses, it is also clear that a specific overt genetic predisposition is not always necessary for their emergence. Dalen (1) demonstrated two sets of etiologic factors in a series of manic patients, one set mainly genetic and the other associated with EEG anomalies and brain damage. Subsequently, Hays (2) drew similar conclusions from a series of bipolar manic-depressive patients and later, on the basis of a series of schizophrenic patients, put forward a similar hypothesis about two separate sets of etiologic factors in schizophrenia (3).

Like EEGs, CT scans are painless and safe, and have been reported to show abnormalities more often among schizophrenics than among controls (4). CT scans are therefore suitable for testing the above etiologic hypothesis.

Method

The subjects were 35 outpatients who had been described as schizophrenic by another consultant and by the psychiatrist who proposed them for the study. None of the subjects had epilepsy, neurologic syndromes, or a history of alcoholism, drug psychosis, or more than trivial exposure to illicit drugs other than cannabis. None was adopted. All subjects had been treated with phenothiazines or similar psychotropic drugs.

One of us (R.C. or P.H.) obtained from each patient a family history that covered all first- and second-degree relatives; most histories were supplemented by relatives' accounts. Patients were then divided into two groups; those with and those without a family history of major functional psychosis.

In the course of a separate investigation of the natural classification of the schizophrenias (5), 18 of these patients had had detailed recording of symptoms at the height of the syndrome. Of these 18 subjects, 16 had thought disorders, 19 had hallucinations (auditory in 12 cases), 11 had catatonic symptoms, 15 had delusions that were regarded as primary, and 7 had passivity phenomena. The 7 patients who did not have catatonic symptoms had auditory hallucinations. Of the 11 patients who did not have passivity phenomena, 9 had primary delusions, 1 had prominent catatonic symptoms, and 1 had a syndrome that consisted primarily of thought disorder, tactile hallucinations, visual misrecognition, and secondary delusions.

CT scans were performed using an EMI head scanning unit with a water bag. Six images (160 × 160 matrix) were obtained for each patient. The scans were angled 15° off the orbitomeatal line and a film recording and number printouts were obtained. No sedation or

contrast enhancement was given. No scans were excluded as uninterpretable on the basis of excessive artifact.

The scans were interpreted independently, without knowledge of the patient's identity, by two neuroradiologists (D.B.R. and D.J.Z.). The patients' ages were disclosed in the second review of cases to aid in assessing the significance of cortical atrophy.

In the initial interpretation, any apparent or suspected variance from absolute normal was recorded. What is normal is still being determined for CT scans and some findings now considered normal may eventually prove to be abnormal. The application of currently accepted norms in the course of the second review caused several changes of category, always from "questionably abnormal" to "within normal limits."

After the second review, the patients were divided into roughly equal groups, one containing those with the most anomalies and the other, those with fewest. A comparison was then made with the genetically based division that had been done independently.

Results

Eighteen subjects had a family history of major functional psychosis in a first-degree relative. Mean ages were 37.3 for the total sample, 39.0 for those with a positive family history, 35.4 for those with a negative family history. The mean interval between the onset of symptoms and the date of the CT scan was 11.5 years overall, so the mean age of onset was approximately 26.

The two analyses of the CT scans did not reveal any reproducible finding common to all or most of the patients. The final interpretations indicated varying degrees of cortical atrophy in 6 of the 7 abnormal scans, a nonspecific finding with many possible causes. The patients with abnormal scans were an average of 6 years older than the normal group, but they had not received significantly more phenothiazines, although their illnesses were generally of greater duration. No other consistent abnormality was encountered in the CT scans. The size of the lateral ventricles was assessed according to the method of Huckman and associates (6). Huckman used approximately 20° angulation and we used approximately 15°, but this difference does not appreciably affect the measurement of the lateral ventricles. Two measurements were taken on two separate levels. Normal size (less than 15 mm by this computation) was only exceeded in one patient (15.5 mm).

Initially, the subjective interpretations seemed to support strongly the hypothesis that there would be more abnormalities among those with a negative family history, but after the results were checked and refined no significant correlation emerged.

Conclusions

Our finding of normal ventricles presumably means that we were looking at a different type of patient from those studied by Johnstone and associates (4). The cortical atrophy we noted may be caused by some feature of the disease process or its management, but on the basis of our findings it does not seem that phenothiazines are implicated.

Although no consistent abnormality was found in the scans of 35 schizophrenic patients and this procedure currently has no place in the diagnosis or management of schizophrenia, computerized tomography, increasingly informative as technical advances improve its resolution, remains of interest in the continuing search for organic features in schizophrenia. The hypothesis that organic findings would predominate in those patients with no family history of schizophrenia was not supported by our results.

Lithium-Induced Thyrotoxicosis

BY VICTOR I. REUS, M.D., PHILLIP GOLD, M.D., AND ROBERT POST, M.D.

Lithium-induced hypothyroidism and goiter have been described by many investigators, but the actual incidence of such side effects is still open to debate (1). Considering that lithium has been used therapeutically in the treatment of thyrotoxicosis, it is somewhat surprising that lithium-precipitated thyrotoxicosis has also been reported (2, 3). This poses a diagnostic and treatment dilemma in psychiatry as any clinically observed change in behavior may reflect a complex integration of primary symptoms of affective illness, central and peripheral effects of increased thyroid function, and the direct and indirect effects of lithium carbonate.

In this article we describe a manic patient who developed thyrotoxicosis when given lithium carbonate during two hospital admissions. Changes in laboratory values of thyroid function are compared with blind ratings of behavior and the postulated hormonal effects on psychomotor activity are discussed.

Case Report

Ms. A, a 22-year-old woman who satisfied Research Diagnostic Criteria (4) for bipolar I affective illness, was admitted to a clinical research ward at the National Institute of Mental Health. She had a 6-year history of manic-depressive illness and had been hospitalized for acute manic episodes 5 times. Ms. A had been taking lithium carbonate, 1500 mg/day, for several weeks and was euthymic on admission. Triiodothyronine (T_3) and thyroxine (T_4) levels on two separate occasions during her first week in the hospital were within normal limits (80–170 ng/100 ml for T_3 and 4–11 μg/100 ml for T_4). Four days after lithium was discontinued the patient entered a classical manic episode characterized by absence of sleep, irritability, hyperactivity, and grandiosity. Repeat thyroid function determinations at this point showed a dramatic increase in T_4 levels (from 6.0 to 13.4 μg/100 ml). The dopamine antagonists pimozide and chlorpromazine were administered in independent sequential trials, without evidence of substantial therapeutic benefit, although weekly T_3 and T_4 values progressively declined to within a normal range.

Lithium carbonate (1500 mg/day, with plasma levels of .9–1.0 mEq/liter) was added after 3 weeks of phenothiazine treatment and resulted in a rapid decrease in mania. However, 6 days after lithium was started Ms. A's T_3 and T_4 levels increased markedly. These values continued to climb and reached peak levels 2 weeks later (T_3=284 ng/100 ml, T_4=16.5 μg/100 ml). Coincident with this increase in thyroid function the patient, after 2 weeks with no ratable mania, experienced a 17-day recurrence of manic behavior that was indistinguishable from her first episode in the hospital. This episode terminated with no specific adjustment in medication and was associated with a continuing decrease in clinical values of T_3 and T_4. Twenty-four hour radioiodine uptake done 2 weeks after peak T_3 and T_4 levels was approximately 1% but increased to 13% at the time of Ms. A's discharge 2 months later. Anti-thyroid antibodies were noted to be present. The patient was discharged on lithium carbonate and was euthyroid by laboratory evaluation at that time.

One year later Ms. A was readmitted because of a manic episode. Levels of T_3, T_4, and free T_4 (normal value=1.0–2.3 ng/100 ml) at the time of admission were within normal limits and remained so when evaluated at weekly intervals throughout clinical trials of low-dose piribedil and carbamazepine. Ms. A's thyroid-stimulating hormone (TSH) response to an infusion of thyrotropin-releasing hormone (TRH) in a drug-free period following admission was also within a normal range. Since the patient experienced only a partial therapeutic response to carbamazepine, she was again given lithium carbonate (1500 mg/day), which led to a rapid decrease in mania ratings. However, during the third week of lithium administration, Ms. A experienced a 5-day period of hypomanic activity characterized by increased motor and verbal activity and loud, intrusive behavior during ward meetings. T_3 and T_4 levels at this point again showed an increase over normal limits (T_3=232 ng/100 ml, T_4=12.3 μg/100 ml, free T_4=3.8 ng/100 ml). These values continued to rise for a week and then returned to normal limits. The patient's TSH response to infused TRH was severely blunted at this time.

Although no further observable mania was recorded, Ms. A continued to complain of anxiety, restlessness, increased perspiration, heat intolerance, and tremor. Thyroid ultrasound and scan showed homogeneous, well visualized symmetrical lobes, with no evidence of enlargement or solid or cystic nodules. Levels of plasma iodine, 24-hour urinary iodide, and thyroid-binding globulin were within normal limits. Endocrinologic consultation at this time suggested a diagnosis of subacute thyroiditis, but it was noted that certain aspects of the patient's symptom complex could be ascribed as well to a primary affective episode or to lithium carbonate therapy. No specific therapy was recommended because a gradual return to normal thyroid function was expected. This did in fact occur over the next several weeks and Ms. A was discharged in a euthymic and euthyroid state on lithium carbonate, 1500 mg/day.

Discussion

Many of the symptoms (5) of hyperthyroidism and its postulated underlying biochemical mechanisms (6, 7) may parallel those of mania. Although in general lithium has been shown to inhibit the release of thyroid hormone and to reduce the intrathyroid iodothyronine/iodothyrosine ratio, lithium-associated thyrotoxicosis

may also occur. The nature of the phenomenon remains unclear, although Brownlie and associates (2) have suggested it may relate to an "escape" of thyroid hormone following expansion of the intrathyroid iodine pool. Alternatively, the increase in TRH and TSH release that occurs secondary to decreasing plasma levels of thyroxine may be associated with direct stimulant-like activity in brain (8). TRH has been shown to possess strong locomotor stimulant action when injected into the nucleus accumbens and appears, in both behavioral and biochemical paradigms, to act as an indirect dopamine releaser (9). The transient and circumscribed nature of the thyrotoxic episodes in this and previously reported cases suggests that the phenomenon is not a primary effect of lithium carbonate but is related rather to an overadaptive response to lithium's hypothyroid actions. Discontinuation of lithium carbonate during these episodes is therefore ill advised because it would be expected to lead to an acute exacerbation of the thyrotoxic state (10). Thyrotoxic "rebound" secondary to lithium withdrawal was demonstrated in the present case at the onset of the first admission and may have played a role in the precipitation of that manic episode.

It is important for clinicians to be aware that symptomatic changes in patients who have recently been given lithium carbonate or have had the drug discontinued may be related in part to alterations in thyroid metabolism. In initial lithium trials, increases in psychomotor activity and anxiety do not necessarily signify a failure in lithium response but may represent transient compensatory increases in thyroid activity.

Toxic Psychosis with Cimetidine

BY C. CLIFTON BARNHART, M.D., AND CHARLES L. BOWDEN, M.D.

We have recently seen several patients referred for psychiatric consultation because of acute confusional psychoses that were temporally correlated with cimetidine use. Cimetidine, a recently introduced H_2-receptor antagonist, has quickly achieved broad use as an inhibitor of gastric acid secretion in peptic ulcer disease (1). Investigation before commercial release did not indicate any CNS effects, toxic or otherwise (2). Two examples of acute, severe confusional psychoses that started soon after cimetidine treatment are described below.

Received Jan. 15, 1979; accepted Feb. 5, 1979.

Dr. Barnhart is Clinical Assistant Professor of Psychiatry and Dr. Bowden is Professor of Psychiatry, University of Texas Health Science Center at San Antonio, 7703 Floyd Curl Dr., San Antonio, Tex. 78284. Dr. Barnhart is also in private practice.

Case Reports

Case 1. A 58-year-old man was hospitalized with abdominal pain that was thought due to cholecystitis. Laboratory studies were within normal limits, except for an elevated white count (12,800 cells/mm³). Two days after he was admitted the patient underwent a cholecystectomy. On the second postoperative day he was given 300 mg of I.V. cimetidine over a 6-hour period. Four hours after the infusion the patient became acutely confused, with visual hallucinations and bizarre speech. The next day he was given 100 mg of chlordiazepoxide, with no improvement in his mental symptoms. He continued to receive cimetidine orally, 300 mg q.i.d. The next day he was given 75 mg of magnesium pemoline orally, without improvement. Psychiatric consultation was then obtained. On examination he was confused and disoriented and had fluctuating levels of consciousness. Cimetidine and magnesium pemoline were discontinued, and within 24 hours the patient's mental status was entirely clear. His further postoperative course was uneventful.

0002-953X/79/06/0725/02/$00.35 © 1979 American Psychiatric Association

Case 2. A 58-year-old woman had a long history of chronic undifferentiated schizophrenia that had been well controlled with perphenazine, 24 mg/day, and amitriptyline, 150 mg/day. She was also taking Maalox and Donnatal for peptic ulcer disease. Symptoms of melena and coffee ground vomitus led to gastroscopy, which revealed an active pyloric ulcer. Cimetidine, 300 mg t.i.d., was started on an outpatient basis. On the second day, after the fourth dose of cimetidine, the patient became confused and disoriented. Although she did not take more medication, she remained confused throughout the day and that night her family found her wandering outside her home. Her psychiatrist was consulted and she was advised to discontinue all medications. Her confusion cleared within 24 hours after discontinuation of her medications. All medications except cimetidine were restarted and she had no further problems.

Discussion

Four physicians in England, where cimetidine has been marketed for a longer period of time, have published letters reporting CNS toxicity (3–6). Two additional cases have been reported in this country (7, 8). The symptoms and clinical course of the CNS toxicity are similar to this report. Within hours after drug institution or dosage increase, the patient becomes confused and disoriented, is often agitated and restless, has unintelligible or bizarre speech, and may have hallucinations, predominantly visual. Upon discontinuation of cimetidine the confusional state clears rapidly, and within 24 hours no symptoms remain. The patient is amnestic for the episode. No sequelae are apparent.

In most of the reported cases of cimetidine CNS toxicity, several identifiable factors are present:

1. *Coexisting psychiatric illness and psychotropic medications.* In addition to the patient described in case 2, we have seen a similar psychosis in a unipolar depressed patient who was taking tricyclic antidepressants. Whether it is the psychiatric disorder or, more likely, the psychotropic medication that increases vulnerability is undetermined. In all cases, the psychotropic agent had strong central anticholinergic effects that can cause a toxic psychosis.

2. *Old age.* All the patients we have seen have been at least 56 years old. Confusional psychoses have been reported in three patients over the age of 70 (5, 8). This apparent age-associated risk could be related to higher peak blood and CNS drug levels or be secondary to impaired CNS function.

3. *Cerebral impairment.* Impaired brain oxygenation might increase the risk of toxicity from cimetidine. Marginal cerebrovascular supply is more common in the aged. One patient we observed had a mild preexisting organic brain syndrome. The patient described in case 1 developed symptoms in the immediate postoperative period, during which the effects of anesthesia or the cardiovascular stress of surgery could impair cerebral function.

4. *Overdose.* In one report, an otherwise healthy 25-year-old man developed a confusional psychosis after taking 12 g of cimetidine (3), and in another (4) two patients, 34 and 50 years of age, inadvertently took double the prescribed dosage and became acutely confused.

Comment

The rapid development of CNS confusion in certain circumstances after cimetidine use, the similarity of the clinical picture in the reported cases, and the rapid, complete clearing of symptoms after discontinuation of cimetidine suggest that the drug causally contributes to the clinical reaction described. The frequency of this reaction is presumably low but unknown. Since readily identifiable circumstances appear to be associated with a risk of CNS toxicity, it seems advisable for physicians to exercise particular caution when prescribing and monitoring cimetidine in high-risk situations. Psychiatrists should be aware of this possible contribution to organic brain syndrome. Further investigation is needed to determine the frequency and the pathophysiology of this effect.

Tardive Dyskinesia Not Associated with Neuroleptics

SIR: The most prominent hypothesis advanced to explain the pathophysiology of tardive dyskinesia suggests a hyperactivity of dopaminergic neurons in the basal ganglia that results from prolonged dopamine blockade induced by chronic neuroleptic treatment (1). We have seen two cases of buccolingual-masticatory syndrome after long-term use of the MAO inhibitor tranylcypromine given in conjunction with lithium carbonate to two patients with bipolar affective disorder. Neither of these patients had received neuroleptic medication.

Case 1. Ms. A, a divorced housewife, was referred for psychiatric assessment at the age of 62 because of depression and chronic back pain for which no physical cause was found. She had had a severe manic attack previously. The patient's only sister had a history of bipolar affective disorder that had responded to lithium prophylaxis.

Ms. A was started on 900 mg/day of lithium carbonate, resulting in a serum lithium level of 1.1 mEq/liter. She continued to be depressed, and antidepressant medication was added. The most successful antidepressant proved to be tranylcypromine, 40 mg/day, which she took for 3 years. During the latter part of this therapy, Ms. A began to develop involuntary chewing movements associated with the sensation of a phantom mass lodged against the upper palate just behind the maxillary central incisors. These symptoms did not cease when the tranylcypromine was stopped for 12 months and lithium carbonate was given alone.

Case 2. Mr. B, a 38-year-old married real estate agent, had been in good physical health before developing a manic-depressive disorder when he was in his 30s. During his hypomanic phase he was more effective, but his depressed episodes seriously impaired his functioning. The patient had been on 30 mg/day of tranylcypromine for 4 months before he was given 1200 mg/day of lithium carbonate simultaneously for prophylaxis (serum lithium=1.0 mEq/liter). Mr. B continued to take this drug combination over the next year and a half. During the reduction of the tranylcypromine dosage he began to complain of persistent involuntary chewing movements that had not ceased when the antidepressant was discontinued.

Tranylcypromine is said to exert its effect by inhibition of monoamine oxidase required for the catabolic oxidation of the putative catecholamine neurotransmitters norepinephrine and dopamine, as well as serotonin. In vitro acute studies have shown this compound to be inactive on [^{3}H]haloperidol and [^{3}H]dopamine binding associated with dopamine receptors in calf brain membranes (2). Lithium has been reported to produce cogwheel rigidity (3) and reinduce tardive dyskinesia in patients (4) and to inhibit norepinephrine and dopamine receptors in rats (5).

The above two cases suggest that chronic administration of tranylcypromine with lithium may result in dopamine receptor hypersensitivity or that there may be other mechanisms to explain tardive dyskinesia than those suggested for chronic neuroleptic treatment.

Sex Roles and Group Therapy Dropouts

SIR: In "The Group Psychotherapy Dropout Phenomenon Revisited" (December 1978 issue), Leslie M. Lothstein,

Ph.D., wondered why so many men dropped out of his groups and attempted to explain the phenomenon on the basis of both patient hostility and group dynamics. However, an explanation based on the sociology of sex roles may be appropriate.

Three factors in masculine socialization may be important here: masculine inexpressiveness, the myth of masculine competence, and avoidance of intimacy with other men (1). A group situation challenges all of these. In group therapy, men are encouraged and expected to ventilate feelings with appropriate affect; this is something men all too often do not know how to do and thus find threatening. In addition, expression of feelings is considered to be a sign of weakness (2). Men are expected to be expert problem solvers and to be competent at all times; participation in group therapy is an admission of one's inability to solve personal problems, which is a major blow to masculine self-esteem. Finally, group therapy forces men to become emotionally intimate with other men, a particularly anxiety-provoking social situation that men are socialized to guard against. Thus, flight from group therapy may be a response to overwhelming anxiety and major threats to one's self-concept. As men use aggression to defend against anxiety, it is certainly possible to perceive these men as hostile.

Accepting the dropout phenomenon as necessary to the development of group cohesion, as suggested by Dr. Lothstein, may not be the solution to this problem. Rather, as I have outlined elsewhere (3), therapeutic interventions to confront and work with specific masculine issues are vital in preparing men for group psychotherapy.

KENNETH SOLOMON, M.D.
Richmond, Va.

Dr. Lothstein Replies

SIR: In my paper I stressed that the white men who dropped out of treatment may have experienced a particular kind of stress early in group therapy which needs "to be addressed in a special way." Dr. Solomon offers an alternative explanation for our findings. He attributes the phenomenon to the sociology of sex roles versus patient hostility and group dynamics. He also seems to suggest that by attending to specific masculine issues, the dropout phenomenon can be reduced or eliminated. Although it is currently in vogue to explain away many social-psychological ills by resorting to sex role theory (1), such an enterprise, by overgeneralizing a point and ignoring group dynamics, grossly oversimplifies a complex human phenomenon.

The importance and complexity of preparing patients for group therapy are well established (2). Dr. Solomon's main point, that during the pregroup patient preparation the therapist(s) should pay special attention to how the sociology of male sex roles may make some men more vulnerable to dropping out of the group, is a worthy clinical addition to the group literature.

Dr. Solomon's theory, however, cannot account for why 50% of our male patients remained in the group or why about 20% of our female patients dropped out. Moreover, his theory has the disadvantage of ignoring individual differences and implying that women do not experience difficulties similar to those of male patients.

In our paper we suggested that not all groups would experience the same stresses for cohesiveness. Therefore, one would expect differences in the reasons for the dropout phenomenon in other groups that we noted in our student-led groups. Dr. Solomon seems to have ignored this point. While I agree with Dr. Solomon that the sociology of sex roles may play an important part in the dropout phenomenon, I disagree that this is the case for all patients. Furthermore, it may also play a role for some of the male therapists!

Entering group therapy can be quite stressful for some patients. The more we know about how we can facilitate a patient's entry into group therapy, the better able we will be to serve the mental health needs of our patients.

Advisability of Combined Treatment

SIR: Although we were interested to learn of a patient who survived a doxepin overdose while taking a tranylcypromine-doxepin combination ("Tricyclic Overdose in a Patient Given Combined Tricyclic-MAOI Treatment" by Kerrin White, M.D., November 1978 issue), we question the use of an MAO inhibitor with a tricyclic at the stage in this patient's treatment when the combination was introduced. Dosage was not cited in the article, but we assume the patient described by Dr. White had failed to respond to therapeutic doses of chlorpromazine and amitriptyline. He was then started on the tranylcypromine-doxepin combination rather than a more conventional treatment regimen such as tranylcypromine alone (1), tranylcypromine combined with lithium (2), or ECT (3, 4). We can find no basis for such early administration of a regimen which, according to current opinion, should be reserved for refractory cases (5). MAOI-tricyclic combinations may well prove to have a role in the treatment of refractory depressions, but failure to respond to chlorpromazine-amitriptyline does not constitute treatment refractoriness.

Dr. White Replies

SIR: Although the patient's history of inadequate response to chlorpromazine and amitriptyline did contribute to my decision to treat him with a tricyclic-MAOI combination, I consider such a history unnecessary to justify clinical use of the combination. Rather, I may start treatment with the combination in the hope of improving the likelihood or rapidity of therapeutic effect, particularly when I am faced with a negativistic patient who is unlikely to cooperate with protracted treatment.

Controlled data bearing on these considerations are lacking. However, reviews (1-3) of uncontrolled clinical series suggest a higher frequency of improvement with combined tricyclic-MAOI treatment than with either medication used alone and indicate a total absence of dire consequences, given elementary precautions. The idea that combination treatment poses special risks seems to have arisen from the unhappy concordance of a few unusual cases with a biochemical theory explaining adverse reactions to combination treatment as another instance of the "tyramine reaction" with MAOIs; this idea then became widely accepted without further proof and has become, in Ayd's words, "one of the several myths or unscientific generalizations that plague contemporary psychopharmacotherapy" (4).

Rejecting the notion of the dangerousness of combined treatment as superstition, one may ask, "Why not prescribe the combination on a routine basis?"

Indeed, we need controlled data bearing on the efficacy as well as the safety of combination therapy for nonrefractory depression. I am currently engaged in an open, randomized pilot study comparing amitriptyline alone (up to 300 mg/day), tranylcypromine alone (up to 40 mg/day), and the combination of both in half dosage with depressed inpatients who have not necessarily been refractory to previous treatment. With results for only 21 available to date, I can say nothing about comparative efficacy, but I have seen no increased incidence or severity of side effects with the combination as compared with either drug used singly.

From a theoretic standpoint, one might even suggest that combining the drugs could improve safety, since tricyclics inhibit the tyramine-induced pressor response (5), considered the prototype of the hypertensive crises that have deterred many from prescribing MAOIs—although this may represent another overreaction to inadequate data.

In Defense of the Internship Year

SIR: In "The Internship Year: A Negative View" (October 1978 issue) Seymour L. Halleck, M.D., stated that there are basically two arguments for the internship: 1) "There is something about the development of a sense of physicianship during the internship year," and 2) "An expanded knowledge of nonpsychiatric medicine is absolutely essential" if a psychiatrist is to function as a consultant to his colleagues.

I disagree with his view that these reasons are not valid. Dr. Halleck criticized the first as vague and the second as false. He stated that the "something" about the development of a physician which occurs during the internship year is "never clearly defined" and "almost mystical." He believes psychiatrists do not need to know a great deal of medicine to act as consultants because consultees "want a consultant who will assess the degree of psychopathology" and "rarely will they welcome a consultant who spends a great deal of time discussing medical issues about which they already possess superior knowledge."

A sense of physicianship is neither vague nor mystical, but blends confidence, humility, and perseverance. A physician needs the confidence to accept responsibility for clinical decisions, the humility to accept errors that may result in harm or even death to patients, and the perseverance to continually try to improve his skills. These qualities can only be acquired by the experience of being a physician. This experience is often painful. Because of the pain, clinical experience with the physically ill will often be avoided by those who need it the most. When the psychiatric resident begins his psychiatric work he may have great difficulty learning to be a physician. Unlike other physicians the psychiatrist can shield himself from taking personal responsibility for life and death decisions. As a resident he can refer serious problems to his supervisor, as a psychiatrist he can join a team of nonpsychiatrists who make clinical decisions democratically, or he can join the "retreat from patients" described by Kubie and become an administrator, teacher, or researcher (1).

The one area where the psychiatrist cannot avoid responsibility for clinical decisions is as a consultant to his colleagues. He must be able to integrate medical, psychological, and social data.

Unfortunately we cannot rely on our nonpsychiatric colleagues' undoubted superior knowledge of medical issues to be operative in the case of the patient they refer to us. Medical and surgical colleagues frequently miss medical diagnoses on patients they refer to psychiatrists (2). Saravey and Koran reported that physicians missed "obvious" organic disease in 4% of medical and surgical inpatients referred to them for psychiatric consultation (2). These authors point out that our nonpsychiatric colleagues tend to refer to psychiatrists those patients who upset them and therefore cause them to exercise poor medical judgment. My own experi-

ence at Kings County Hospital Center is similar (3). Meyer and Mendelson described a state of "active alienation" in the doctor-patient relationship in all inpatients referred to psychiatrists (4). This alienation causes poor clinical judgment.

As a psychiatric consultant, I have supervised the work of 150 second-year residents over the past decade. Between 25% and 30% had no internship. With 3 or 4 exceptions their work as consultants ranked in the bottom half of their group. About one-fourth of the total residency group was outstanding but only 2 of those without an internship qualified for this description. Karasu and associates reported similar findings (5).

Psychiatric residents without internships are rarely able to integrate medical, psychological, and social data to produce a treatment plan. Almost all show great difficulty in accepting responsibility for seriously ill patients and for advising colleagues. A few try to deal with the problem by avoiding patients. Most deal with their fears of responsibility by acting as a conduit for the opinions of their supervisor, who acts as an auxiliary professional ego. This meets the service needs of hospitals, but the internshipless psychiatrist never develops a professional ego of his own and never becomes a competent physician or an effective consultant.

Dr. Halleck is quite right that psychiatry departments should not be responsible for training in medicine, pediatrics, or family practice. Psychiatric residencies should return to a three-year program, accepting as residents only those who have completed at least one year of training in a medical, pediatric, or family practice program. He points out that "understaffed county hospitals in inner cities would welcome American graduates whether or not they are going into psychiatry." After completing such a year psychiatric residents will indeed have become physicians and will have the necessary foundation to become psychiatric specialists. Our patients would gain by the care of highly motivated physicians. Medical graduates who wish to avoid clinical experience might do better in a nonclinical specialty or one in which stressful decisions are not such a large part of patient care. Our specialty might gain both stature and recruits by a commitment to clinical excellence rather than by the commitment to filling residency programs at the cost of clinical excellence, which has caused the loss of both.

LEWIS GLICKMAN, M.D.
Brooklyn, N.Y.

Dr. Halleck Replies

SIR: I agree that the decision to ask psychiatry departments to develop their own internships in primary care areas was unwise. I would certainly prefer a system in which residents were required to take a full year of a rotating internship or a primary medical care internship to the system we have now.

In other areas, Dr. Glickman and I disagree. I do not believe that physicians have a monopoly on developing an optimum blend of confidence, humility, and perseverance. Other professions such as the ministry, education, or law could make similar claims to having a unique capacity to develop such virtues. Dr. Glickman's blend of desirable qualities simply describes a competent professional who is also a decent human being. His argument does not clarify the mystical nature of "physicianship."

Dr. Glickman's observation that nonpsychiatric colleagues tend to miss diagnoses on patients they refer to psychiatrists does raise serious questions. It provides a rational argument for having psychiatrists know as much nonpsychiatric medicine as possible. But putting the burden on the medical expertise of the psychiatrist is only a palliative response to the problem. The real issue here is medical education. If nonpsychiatric physicians are so careless in examining psychiatric patients, this represents a terrible indictment of medical education. Training psychiatrists to compensate for the poor clinical attitudes of other physicians will not resolve this problem. Rather, we should be concerned with why we are graduating physicians who experience a state of "active alienation" from psychiatric patients.

Dr. Glickman provides some anecdotal data about the failures of residents without internships. I could provide more anecdotal data about their successes but this would not clarify anything. There are no scientific data in this area, and I would still be critical of making policy decisions without attempting to obtain such data. Dr. Glickman's contention that the "internshipless psychiatrist never develops a professional ego of his own and never becomes a competent physician or an effective consultant" may be a little overstated. We have now graduated hundreds of such individuals, many of whom have assumed positions of leadership in our profession. I pray that Dr. Glickman is wrong and that they are not all incompetent and ineffective.

Two years have now passed since I wrote my article. Although I have received considerable feedback which convinces me that I was right in being critical of the practical value of reinstating the internship year, I am no longer so committed to my theoretic critiques. It may reassure both Drs. Romano and Glickman to know that I do see a good many residency applicants who are uncertain as to their future identity as physicians and very much want a good internship. At the same time, however, I also see other applicants who do not seem to want or need an internship. If we ever get around to studying this issue rather than debating it, I suspect we would find that some applicants need an internship and some do not. Certainly the provision of a good internship year is essential for those applicants who feel they need it.

Further theoretic discussion of this issue without the availability of new data is wasteful. For better or worse, a fourth year of training is now required and there are no alternatives to concentrating on making it a good one. Our biggest problem is finding training sites for nonpsychiatric medical experience for our residents. I hope that we can stop arguing with one another and join forces in working toward persuading our medical schools to develop decent internship positions for psychiatric residents.

Chapel Hill, N.C.

Predicting Imipramine Response

SIR: The article by Frederic Quitkin, M.D., and associates on "Imipramine Response in Deluded Depressive Patients" (July 1978 issue) could be misleading. Many clinicians want to know if the occurrence of psychosis causes poor response to imipramine in depressed patients; the authors concluded that their data did not support this hypothesis. Although they cautioned against generalizing their data to other groups of deluded depressive patients, the general tone of the article did not follow this caution.

Several problems weaken the data. The Perceptual Distortion Scale used as one criterion to determine the presence of psychosis included the items "disorientation for people" and "disturbed by hostile impulses." Patients with a positive rating on any item were considered psychotic, but these items are not necessarily signs of psychosis. Another item was "implausible belief." This may have included only delusions, but since the severity of delusions was "generally rated as slight to mild," one cannot be convinced that this item included only definite delusions. Thus, the sample selected by the Perceptual Distortion Scale may have included persons who did not have true psychosis. If this was the case, then one would not expect to find differences in response to imipramine between the two groups ("psychotic" versus nonpsychotic).

The next set of criteria for psychosis seems more valid: the presence of separate psychopathologic features, i.e., conviction of sinfulness or persecution and belief in external control. Unfortunately, only one symptom yielded a treatment group with more than four patients. Such small sample sizes make it difficult to detect statistically even a large difference in response to treatment. Therefore, the authors presented a misleading conclusion in stating that no statistical difference was found in the response to imipramine on the basis of presence or absence of separate psychotic symptoms. I regret that hallucinations were not included in the analysis of separate symptoms; my own preliminary (and inconclusive) data suggest that hallucinations predict poor response to tricyclics.

Dr. Quitkin and associates stated that delusions and hallucinations were not prominent features in their patients and that these features were generally rated as slight to mild. This may explain the discrepancy between their results and those of other researchers, who have found that delusions predict a poor response to tricyclics (1–5). I agree that caution is required in generalizing the data to other groups of deluded depressed patients.

Many of the data presented by Dr. Quitkin and associates are provocative but weak. The stronger data seem to involve the "depressive" type of delusions, such as conviction of sinfulness. My own preliminary data suggest that depressive delusions (those of nihilism, self-deprecation, and somaticism) may respond to tricyclics, while other delusions may not respond. Therefore, the important issue for tricyclic response may not be delusions per se but depressive versus nondepressive delusions and hallucinations.

RICHARD E. MINTER, M.D.
Ann Arbor, Mich.

Dr. Quitkin and Associates Reply

SIR: Dr. Minter's criticisms were met in our paper. First, our definition of "delusional" is a liberal one, and a different sample with more severe psychotic symptoms might have shown different results. Second, the lack of a statistically significant difference between the delusional and nondelusional group in this sample does not prove there is no difference. The possibility of a type II error is present, i.e., asserting there is no difference when in fact there is.

His suggestion that nondepressive delusions are particularly refractory to treatment is interesting but also requires systematic substantiation. A definitive answer will come only from further research. Our major point is that the present data are inconclusive and it is therefore premature to avoid a trial of a tricyclic antidepressant in a psychotic depressive. Most patients have a strong preference for drug treatment compared with ECT. Rejecting such preferences requires strong grounds.

Incidentally, Dr. Minter states that we had no more than 4 patients with any one psychotic symptom when in fact 11 imipramine-treated patients had conviction of sinfulness.

Warning Against Generic Substitutes

SIR: I would like to report a case in which substitution of the generic tricyclic for a brand name adversely affected a patient.

The patient, a 66-year-old woman, first became depressed 8 years ago. The depression was associated with diurnal mood variation, early morning awakening, anorexia, and weight loss. The patient responded well to a proprietary brand of imipramine. In January she became depressed again and resumed taking the proprietary brand of imipramine, to which she responded at a dosage of 150 mg/day. In October, the depression and vegetative signs reappeared. She had not altered the way she had been taking the medication, and we could not find any life event or anniversary that could explain the exacerbation of the depression. We increased the dosage of her medication to 200 mg and then to 250 mg/day over the course of 2 weeks, but she did not respond.

At this time I learned that the patient had not been getting the proprietary brand but a generic substitute. Instead of increasing the dosage I again prescribed 250 mg/day of the proprietary brand but this time ordered that there be no substitution. Within 3 days the patient's sleep began to improve and she felt less hopeless and less depressed. Two weeks later, all of her vegetative signs were in remission and her mood was "normal."

This patient's case demonstrates the possibility that generic substitutes are not always equivalent to the brand name product. Unfortunately, the testing and blood levels that would be necessary for rigorous proof of this assumption were not available in this case. I hope that such a study can be done.

SAMUEL I. MILES, M.D.
Los Angeles, Calif.

Neuroleptic-Potentiating Effect of Metyrosine

SIR: Metyrosine (α-methyl-*p*-tyrosine, AMPT), an inhibitor of tyrosine hydroxylase, decreases the synthesis of dopamine and, according to the dopamine hypothesis of schizophrenia, may be useful in treating schizophrenia. In addition, supplementing neuroleptic medications with metyrosine might allow a reduction in total neuroleptic dose, although earlier trials with this approach produced conflicting results (1, 2). We conducted an investigation to examine the antischizophrenic and extrapyramidal effects of metyrosine compared to haloperidol and placebo.

Twelve schizophrenic patients, ranging in age from 20 to 60 years and with a minimum of 2 years' illness duration, gave informed consent to participate in a double-blind crossover trial. After a gradual reduction in the previous neuroleptic dosage produced a clear exacerbation of psychotic symptoms, patients were given either metyrosine or haloperidol in randomized order for 4 weeks; doses were increased until the optimum effect was obtained. Placebo followed this active drug treatment until psychotic symptoms again intensified, at which time each patient received the alternate test drug for 4 weeks. Semi-structured interviews, recorded on videotape before and at the end of each treatment period, were assessed blindly by independent psychiatrists using the Brief Psychiatric Rating Scale (BPRS). Neurologic signs were documented on a specifically designed rating scale (3), and the patients' behavior was recorded by the nursing staff on the Nurses' Observation Scale for Inpatient Evaluation (NOSIE). Routine laboratory tests were monitored.

The initial neuroleptic dosage reduction was 50%–75% (mean=68%). Metyrosine dosage was 1.5–3.0 g/day (mean= 2.75 g/day) and haloperidol dosage 1.5–15 mg/day (mean= 5.0 mg/day). The BPRS and NOSIE scores were significantly reduced during treatment with both metyrosine ($p<.05$) and haloperidol ($p<.05$) compared to the respective placebo scores. There was no significant difference between metyrosine and haloperidol BPRS scores. The psychiatric state of 2 patients deteriorated during metyrosine treatment but improved when their previous neuroleptic dose was restarted. Parkinsonism was slightly but significantly increased during haloperidol administration compared to placebo ($p<.05$); a nonsignificant trend in the same direction was seen with metyrosine. There was no significant difference in parkinsonism or akathisia scores when metyrosine and haloperidol were compared. Correspondingly, the use of anticholinergic drugs during the two treatments was not significantly different. Neither metyrosine nor haloperidol induced abnormal laboratory values.

This study confirms the previous report that metyrosine has neuroleptic-potentiating effects (1). However, severe schizophrenic symptoms could not be managed satisfactorily with metyrosine. The modest antipsychotic effect and the potential for aggravating extrapyramidal symptoms suggest that the combination of metyrosine and neuroleptics does not offer a clinical advantage in the treatment of schizophrenia, although tyrosine hydroxylase inhibitors may still prove useful as a research tool in elucidating the pathogenesis of psychoses.

Celiac-Type Diets in Schizophrenia

SIR: In "Another Look at Gluten in Schizophrenia" (November 1978 issue) James R. Rice, M.D., and associates reported that a schizophrenic patient who had been hospitalized for more than 13 years improved substantially on an 8-week experimental "gluten-free and milk-free diet" and was discharged. Another patient, hospitalized for 14 years, regressed when gluten was added to the hospital diet and improved considerably on the subsequent gluten-free and milk-free diet but was not discharged because she discontinued her diet when not supervised. The results in the other 14 chronic schizophrenics in the study were not discussed.

The authors state that their work did not duplicate the success reported by Dohan and Grasberger (1) and Singh and Kay (2). I would emphasize such duplication could not be expected because of crucial differences in patients, experimental design, and diet. My comments pertain only to the differences between their investigation and mine.

Dr. Rice and associates studied 16 chronic schizophrenics whose current hospitalizations ranged from 6 months to 10 years. My study included over 100 recently relapsed schizophrenics who were randomly assigned to control or experimental diets on the day of their admission to the hospital.

Although the diet used by the South Carolina investigators did not include obvious cereal grains or milk, it did contain some milk protein and wheat gluten. They used butter, and the bread was made with wheat starch that contained 0.2% gluten (personal communication). Symptomatic and morphologic effects of apparently small amounts of wheat gluten in celiac disease, which I have proposed as a possible model (perhaps genetically related) for studying the pathogenesis of schizophrenia, are well known. For example, Dissanayake and associates (3) have stated that for adult celiac patients as little as 0.5 g of wheat gluten a day is a "large amount" because even smaller doses prevented the return to near normal of the gluten-damaged intestinal mucosa.

My experiments were designed to eliminate all traces of glutens in all cereal grains because schizophrenia does occur (although possibly less frequently) in societies in which rice and/or other cereal grains (4) but little or no wheat, rye, or

barley (the grains omitted in the so-called gluten-free diet for celiacs) are eaten. All traces of milk were eliminated because milk sometimes worsens celiac disease. Furthermore, Zioudrou and associates (5) at the National Institute of Mental Health, stimulated by evidence relating cereals to schizophrenia (1, 2, 4), have reported naloxone-reversible endorphin ("exorphin") activity in peptic digests of milk casein and corn and barley glutens and, most notably, an exorphin peptide from wheat gluten that is about as potent as met-enkephalin. Other fractions from all tested glutens had a stimulating effect.

Dr. Rice and associates' study used only 8 weeks of diet, but patients with adult celiac disease, as well as the genetically related chronic disorder dermatitis herpetiformis, often do not show significant clinical improvement (which occurs in most but not all cases) for many months after a celiac-type diet is instituted. For this and other reasons I suggested in 1973 that an experimental therapeutic trial of diet in persistently symptomatic chronic schizophrenics should continue for 6 months to a year (1).

I thank the South Carolina investigators and dietitians for their interest in the food-derived peptide hypothesis of the etiology of schizophrenia and for their generosity in supplying me with the unpublished information I have cited above.

F.C. DOHAN, M.D.
Philadelphia, Pa.

SIR: I read with interest the report by Dr. Rice and associates on gluten in schizophrenia. However, for reasons enumerated below, I found the study to be a less than satisfactory attempt at testing the "gluten hypothesis" or replicating our investigation (1–3).

First, if the continuous presence of a pathogenic factor has already resulted in a profound, long-lasting illness, there seems no reason to expect that increasing the quantity of that factor would have any further effect. Furthermore, for reasons such as the "ceiling effect" of ratings, any worsening of already severely ill patients may not even register. Therefore, the first part of their experiment, in which they added more gluten to a normal gluten-containing diet, was not a valid test of the hypothesis that cereal-grain gluten may be pathogenic in schizophrenics. It would have been much better to start the patients on an exclusion diet and then challenge them with the hypothesized pathogen. It would have been better still to use the ABA design we employed in order to permit control of the order effect of treatments (2, 4).

Second, the chances of proving any etiologic hypothesis in terms of treatment effects may be small if the test is conducted exclusively in patients with histories of long-standing intractable illness and institutionalization because of the likelihood that disease effects have become irreversible and the pathologic patterns of thinking and behavior have become habitual. This is not to say that malignant and chronicity-prone forms of schizophrenia should not be studied, but rather that they should be studied earlier in the course of illness to minimize the chances of erroneously rejecting a hypothesis because of the effects of chronicity. Thus, most of the patients in our study were acute or subacute, but 80% of them were of the poor prognosis or nuclear variety. Only 3 of the 14 patients tested were of the type involved in the investigation of Dr. Rice and associates.

Third, schizophrenia is recognized to be heterogeneous, so the results of any treatment depend on the degree to which patients responsive to that treatment are represented in the sample. Sample composition is a particularly critical issue in small studies. Dr. Rice and associates included schizo-affective patients, whom we excluded, and studied very few nonparanoid patients (hebephrenic and catatonic), who comprised 80% of our sample and accounted for most of the "gluten responders."

Considering these factors, which unduly increased the likelihood of type II error, one cannot regard this study as a fair test of the gluten hypothesis. Indeed, under the circumstances it is remarkable that a clear dietary effect was found in 2 of the 16 patients. This study does not warrant the authors' pessimism about the gluten hypothesis but should instead encourage further investigations with careful attention to the above-mentioned and other methodological issues (2–4).

Dr. Rice Replies

SIR: I wish to thank Dr. Dohan and Dr. Singh for their comments and critiques. I feel their observations should be kept in mind in future projects. Hindsight is often better than foresight. I hope my project will stimulate increased interest in the refinement of this subject.

JAMES R. RICE, M.D.
Columbia, S.C.

Applause for the End of a "Drought"

SIR: I read with great interest the article "Training Psychiatrists for Working with Blacks in Basic Residency Training Programs" (December 1978 issue) by Walter H. Bradshaw, Jr., M.D. This article was refreshing, particularly given a

three-year drought of articles about black mental health issues written by black authors. Could it be that the process of selecting this type of work for publication should be scrutinized?

This decline in the publication of work related to black mental health is apparent not only in the *Journal* but also at most recent annual meetings of the American Psychiatric Association. I long for the day when sessions on the subject of black mental health will be offered for continuing medical education credit; this would signal the importance of knowledge about black patients. Regrettably, the cause of black mental health has not been kept before our membership, and this has undoubtedly led to a complacency among black psychiatrists.

I would point out that the American Psychiatric Association has probably been the most sensitive and forceful medical specialty group in recognizing the health problems of minorities, including women and the elderly.

JAMES H. CARTER, M.D.
Durham, N.C.

A Question of Balance

SIR: "Genetic Counseling for Psychiatric Patients and Their Families" by Ming T. Tsuang, M.D., Ph.D. (December 1978 issue) admirably sets forth some of the central issues, as well as reviewing core information in this area. A good candidate for inclusion in the author's list would be epiloia (tuberous sclerosis), a disease that is not uncommon among institutionalized retarded persons and is probably transmitted in an irregular dominant mode (1). Despite the paucity of attention it has received in the psychiatric literature, tuberous sclerosis seems to have a relatively high frequency of associated psychopathology (2, 3).

This oversight is indicative of a broader problem relating to the role of psychiatry in mental retardation. A computerized search I conducted of the past 5 years' literature elicited fewer than 50 "hits" for the topic of combined disability, with less than 15 articles on combined mental retardation/psychiatric impairment in major English language psychiatric publications. For those who see this phenomenon in terms of economic determinism, this sad state of interest can be compared to the number of publications on drug-related topics. Is anyone listening?

Possible Mechanism of Lithium's Effect in Bronchial Asthma

SIR: We would like to comment on the article "Coincidental Improvement in Asthma During Lithium Treatment" by Suhayl J. Nasr, M.D., and Robert W. Atkins, M.D. (September 1977 issue), who reported 2 cases of a prophylactic effect of lithium on bronchial asthma; and on a letter by Peter L. Putnam, M.D., who reported 2 additional cases of remarkable remission of asthma in patients started on lithium carbonate (letter to the editor, March 1978 issue).

Drs. Nasr and Atkins suggested several possible biochemical mechanisms for this effect. However, they did not mention that one of the leading theories of the biochemical defect that predisposes individuals to asthma suggests an unresponsive β-adrenergic receptor (or β-adrenergic adenylate cyclase) in the bronchi (1). Lithium has been shown to inhibit β-adrenergic adenylate cyclase in vivo in patients with therapeutic blood levels (2), and thus one might expect lithium therapy to aggravate, not ameliorate, asthma.

We wish to report recent data from our laboratory that might explain this paradox. In the cerebral cortex of rats treated for three weeks with lithium in food, β-adrenergic adenylate cyclase was found to be inhibited after noradrenaline stimulation. However, basal levels of cyclic AMP (in the absence of noradrenaline stimulation) were significantly increased (3). Thus lithium appeared to have a biphasic effect, activating adenylate cyclase when the enzyme is inactive and inhibiting the enzyme's full activation. These results would be consistent with lithium's prophylactic effects in both depression and mania.

We predict that chronic lithium therapy would prevent recurrent asthma but would reduce the effectiveness of epinephrine treatment in the acute asthmatic attack. This theory reconciles the β-adrenergic theory of asthma and the increasing evidence that lithium affects β-adrenergic adenylate cyclase.

The Medical Model Revisited: A Question of Citation

SIR: It is virtually axiomatic that good scholarship includes understanding and recognizing previous contributions, especially in any effort to set forth a new position.

In this respect, "The Illusion of Simplicity: The Medical Model Revisited" by Herbert Weiner, M.D. (July 1978 Supplement) is wanting as a piece of scholarship. The author did not mention the contributions of Miriam Siegler and Humphry Osmond, summarized in *Models of Madness, Models of Medicine* (1).

Siegler and Osmond (1) emphasize that the medical model includes a special encounter and relationship between physician and patient. The physician, acting powerfully and authoritatively (but not authoritarianly) confers the sick role on the patient. The patient with the sick role is excused from usual activity, responsibility, and behavior and is entitled to

the sympathy of other people and society, but is obliged to cooperate to get well. The doctor offers diagnosis, prognosis, therapy, and hope. Diseases are assumed to have natural causes if etiology is uncertain or unknown.

In light of Siegler and Osmond's statement, Dr. Weiner's error was to say nothing of that special encounter between doctor and patient. He explains the medical model merely as an outdated view of disease that should be expanded to incorporate observations and experimental data from diverse levels of organization, such as cultural, evolutionary, and molecular factors.

Weiner's views are reminiscent of those of Engel (2), who also did not acknowledge Siegler and Osmond. Curiously, both Weiner and Engel discuss and cite Ludwig (3) as the first author on their respective reference lists. Ludwig (3) discussed Siegler and Osmond with appropriate citation. Why did neither Weiner nor Engel pick up this important lead to the literature?

It may be a fitting irony that Dr. Weiner's article was published in the Festschrift for Francis J. Braceland, M.D., who is mentioned in Siegler and Osmond's acknowledgments (1, p. xi).

Distinguishing Between Mood and Affect

SIR: "Mood and Affect: A Semantic Confusion" by Howard Owens, M.D., and Jerrold S. Maxmen, M.D. (January 1979 issue) helped to clarify this muddy area by recognizing the inferential nature of information about emotional states and offering clinical guidelines for more lucid descriptions of such states.

I would, however, question their conclusion that "perhaps the main distinction between mood and affect is that inferences about mood stem from present observations and past events . . . while inferences about affect usually pertain only to current observations." Custom and usage offer a more valuable distinction.

The common modifiers of the term "affect," e.g., shallow, constricted, monotonous, blunt(ed), flat(tened), (in)appropriate, of full range, suggest that we are describing not so much the emotional state per se as the subject's capacity to cope with that state, the extent of the subject's apparent awareness of his own emotions, and his ability to communicate them to others. When we use the term "affect" to describe the range, intensity, and appropriateness of the emotional state and how the subject communicates evidence of this state to the observer, we make a valuable distinction between "affect" and "mood."

Drs. Owens and Maxmen defined mood as "a disposition persisting over time" or as "a prolonged emotion," but we refer here not to conventional units of time but rather to persistence of the emotional state through periods when internal or external events would ordinarily be expected to alter that state. Thus we can describe in a brief mental status examination a mood that prevails throughout the interview despite the occurrence of events that invite change in the emotional state.

HERBERT BENGELSDORF, M.D.
Valhalla, N.Y.

Drs. Owens and Maxmen Reply

SIR: There is clearly a difference between the experience of emotion and the manner of expression of emotion. We would reiterate, however, that the word "affect" is commonly used not merely to refer to manner of expression but rather in ways that are indistinguishable in meaning from mood. One often hears the statement, "The patient's predominant affect during the interview was depression." Such statements do refer to emotional state per se.

If we understand Dr. Bengelsdorf correctly, he is arguing that a mood is a persisting emotional state and that affect refers to alterations (or the lack of alteration) in the awareness, appropriateness, or expression of that mood. Our major contention has been that it is simply clearer to refer to such changes themselves as changes in expression, recognizing that even in a short interview a patient may show an array of complex, contradictory, or confusing emotions, sometimes in rapid sequence. A manic patient may be laughing and joking, then abruptly burst into tears; if such a patient is extremely labile we may be hard pressed to describe any persisting mood. A person in mourning may appear saddened, then begin to laugh at the recollection of an old family joke about the deceased. Clearly there is great variation in the range, intensity, and appropriateness of emotional expression. We continue to believe, however, that it adds little to label a person's sadness as mood and his laughter as affect.

How are we to distinguish between observations which tell us about mood and those which indicate affect? The distinction is deeply engrained, but in both instances we are really making inferences from the same array of observations.

HOWARD OWENS, M.D.
JERROLD S. MAXMEN, M.D.
White Plains, N.Y.

More on Mood and Affect

SIR: In "Mood and Affect: A Semantic Confusion" Howard Owens, M.D., and Jerrold S. Maxmen, M.D., stated that "inferences about mood stem from present observations and past events (and therefore belong in a patient's history rather than as part of his mental status examination), while inferences about affect usually pertain only to current observations." I was taught the same distinction, but by means of a simple, easily remembered analogy: mood is to affect as climate is to weather.

BOOK REVIEWS

Controversy in Psychiatry, *edited by John Paul Brady, M.D., and H. Keith H. Brodie, M.D. Philadelphia, Pa., W.B. Saunders Co., 1978, 1,071 pp., $39.50.*

Disagreements on controversial issues are often published as an exchange of letters following an author's stated views in a scientific journal. Brady and Brodie chose controversial topics that are timely and important from a scientific, medical, or societal perspective. Another criterion for selection specified that reasoned arguments could be made from different vantage points. Two or more experts known to have a position on the issue prepared essays defending a point of view without benefit of seeing the opposite opinion. A brief summarizing commentary by one of the editors concludes each chapter.

There are 26 questions, such as, What is the future of psychiatry as a medical specialty? What is in the future of psychoanalysis? Is psychosurgery ethical and effective? Does ECT have a place in the therapy of schizophrenia? Are drugs more than palliative in the treatment of schizophrenia? Are CNS-activating drugs of value in the treatment of the hyperactive child? Is behavior therapy a fad or a new direction for psychiatry? Is there evidence for specificity in psychotherapy? Does psychotherapy alter the course of schizophrenia? What are the indications for group therapy? Should homosexuals adopt children? What are the medical hazards of marijuana? Should psychiatric patients ever be hospitalized involuntarily? Can informed consent be obtained from a psychiatric patient? Is community psychiatry a slogan or a new direction?

I found myself asking whether the topics selected were representative of major controversial issues in psychiatry today. Would the experts chosen be ones who would offer opinions I would value? Were the arguments offered well stated? Did the method of presentation add useful new information?

The topics selected are good ones. Perhaps one's own list of controversial issues could produce some suitable replacements for long-term drug therapy in the treatment of depression, the management of chronic alcoholism, biofeedback, or genetic counseling.

The essayists are well chosen and most are recognized experts in the area addressed. I would have selected someone other than the doctor from NIMH for a presentation on the future of psychiatry. Most are familiar with his attacks on psychiatry. Respect for the wisdom of an essayist strengthens the acceptance of an opinion. A discussion of involuntary admissions to mental hospitals and a focus on dangerousness might have been more convincing than the presentation by the familiar exponent of psychiatry as a myth. The commentary by one of the editors highlighting the major points made by the essayists and adding his own critical evaluation brought the differing viewpoints more clearly into focus.

In general the answers to the questions were well stated and backed up with supportive data. Some essayists did a superb job in providing a comprehensive overview of their topic. Particularly noteworthy was the chapter on management of alcoholism, which was an excellent summary of current research. The overview on drug therapy in schizophrenia and the review of the hyperactive child syndrome were outstanding.

Occasionally there was more detail than necessary to arrive at a reasoned position on an issue. It is a long book; it could have been a better one with pruning. The method of presentation consolidates in one place arguments for and against positions or issues recognized as controversial. It is useful in formulating one's own opinion.

It is a good book; I enjoyed reading it. It is highly recommended as a resource in the resolution of current controversial issues in psychiatry for psychiatrists and all mental health professionals as well as by those in administrative posts in the mental health system.

Hartland, Vt.

Karen Horney: Gentle Rebel of Psychoanalysis, *by Jack L. Rubins. New York, N.Y., Dial Press (Dell Publishing), 1978, 350 pp., $9.95.*

Karen Horney is one of the great figures in the history of psychoanalysis and psychiatry. Her theory contributed a new dimension to our understanding of human nature. Jack Rubins, a long-time student of Horney's theory and a contributor to its development, has done us a fine service: he has brought together a mass of details about Horney's life as well as the cultural and historical conditions in which she lived. She lived in a time of vast change, encompassing World Wars I and II, world-wide depression, and the rise of Hitler. She immigrated to the United States at a time of changing values and growing awareness of the destructive capacity of man's technology as well as the creative investigation of the human mind uncovered by Sigmund Freud.

Rubins conveys how Horney's curiosity, vitality, and intellectual capability led her to an ever-widening search for answers to the problems she encountered in her life and in confrontations with her patients. His language and style make vivid the urgency Horney felt as she moved from the limited views of Freud into an awareness of the paradoxes opened by Kierkegaard, Tillich, and other philosophers, whom she read with care. Rubins implicitly shows how, in her clinical work and in her thinking, Horney was able to juxtapose differences without rushing to place them into some rigid framework. Like Freud, she put actual observation first and only later in her life did she begin to synthesize. Her freedom to observe allowed her a true rigorousness.

It is clear from this book that Horney's theories grew out of her need to comprehend the fragments of her life and her observations. Rubins shows how Horney came on the idea that the life process was a solution in itself. In *Our Inner Conflicts* and *Neurosis and Human Growth,* she began to detail overall forms of life as constellations of behavior that attempt to solve the essential problem of basic anxiety. She saw that the orientation of scientific psychoanalysis was primarily toward symptoms, that it was concerned with thought objects and such fragments as drives, and that the analyst

attempted to understand by connecting one symptom to another through cause and effect. Her revolutionary insight was to go beyond the obvious, the visible, and to look at the invisible, and to observe beyond particularities into the holistic workings of the personality. As she saw the use of solutions for deeper insecurity and the emergence of so-called drives and impulses from a ground of feeling, Horney gained more understanding of the whole structure of neurosis. She began to recognize the falseness of this structure and to ask what would produce a unified person—a person who is wholehearted and not fragmented into such parts as ego, id, and superego or idealized self and despised self.

These questions led her to Zen Buddhism, an interest that seemed to be a natural outgrowth of her life work. At the outset of her work, she made many different clinical observations. As Rubins shows, her early papers are detailed descriptions of different patients that contain an unusual understanding of each one. Although she developed a typology, she was careful to note that everyone exhibits something of every type. Only after seeing the diversity did she begin to ask how these pieces fit together to form a solution. Although she found many nodal points, such as the comprehensive pride system and the basic conflicts, it was clear to her that neurosis is ultimately a state of fragmentation. In Zen, she came into an arena that appreciated the true nature of this fragmentation and even offered a way to go beyond it. Horney saw that psychoanalysis, at least as developed by Freud, was involved in the fragmentation itself and that a more comprehensive, holistic therapy was needed.

Although Rubins' biography is excellent, it lacks that ingredient which would have left us feeling that we understood what Horney went through. One can sympathize with the problems Rubins faced in writing about Karen Horney: she seems elusive, secretive, and closed about her personal struggle; but we yearn to know more of what went into her creative processes. Her theory differed fundamentally from other work in that she appreciated the fact that neurotic process was a transformation from a healthy growth via deeper basic anxiety into compulsive, driven behavior.

While Freud and the mainstream of psychoanalysis were caught in a mechanical paradigm in which quantitative distinctions were made, Horney saw the qualitative distinctions between health and illness. What was it in Horney's life or spirit that gave her this insight? She was always more related to artists and philosophers than to other theorists, and these affinities seem to lie at the core of her understanding. Perhaps it was the relationship with her mother that was the basis of her deep faith in growth. That relationship seems to have contributed to her sensitivity to the problems of women. Unfortunately, Rubins does not help us with these kinds of questions, nor does he clarify what went into the inductive leaps Horney made when she developed her unique concept of the real self. However, Rubins goes a long way toward bringing this important person into focus and titillating our appetite to know more about Karen Horney.

DAVID SHAINBERG, M.D.
New York, N.Y.

Edward Jarvis and the Medical World of Nineteenth-Century America, *by Gerald N. Grob. Knoxville, Tenn., University of Tennessee Press, 1978, 287 pp., $14.00.*

Gerald Grob, professor of history at Rutgers University, belongs to that group of intellectual and social historians who have brought to the history of psychiatry a new rigor and enthusiasm by applying the tools and insights of social and intellectual historians to the history of American psychiatry. Among his books are *Mental Institutions in America: Social Policy to 1875* (1) and *The State and the Mentally Ill* (2).

Edward Jarvis (1803–1884), a leading physician, psychiatrist, and statistician of Massachusetts, presented his "A Report on Insanity" to the Massachusetts Legislature in 1855. It was the most significant statistical social survey of mental illness in the nineteenth century and became the prototype for later investigations. Although the dust jacket of this book states that he was "one of those responsible for reshaping the profession," Jarvis was never in the mainstream of American psychiatry. He was passed over for the medical superintendency of McLean Hospital, Worcester State Hospital, and Northhampton State Hospital.

After graduation from Harvard College and Harvard Medical School, Jarvis began his career in general practice. He became interested in mental disease and later devoted himself exclusively to that specialty, in which he soon acquired a national reputation. He achieved his greatest fame in the study and collection of medical statistics, particularly those concerned with insanity, and he served as an influential adviser to the federal census officials from 1850 to 1870. During his entire career as a psychiatrist, he treated inpatients in his own home.

Grob has done the best he could with a rather dull and wooden figure. His scholarship is meticulous, and the social and intellectual background of Jarvis' period is beautifully drawn. Grob's presentation elicits little empathy for the hair-splitting, rigid, sanctimonious character of Edward Jarvis, but the book is a superb biographical account. Grob magnificently reveals the dilemma of nineteenth-century American psychiatry—caught between the specific germ theory, which was transforming the medical profession to the search for specific causes of disease, and psychiatric practice and philosophy, which were geared toward holistic preventive medicine.

The book is well designed, is on good paper, has notes at the end of each chapter, and has an adequate index. This book will appeal to historians of psychiatry and to those practicing psychiatrists who wish to know about their intellectual roots.

Boston, Mass.

Jungian Psychotherapy: A Study in Analytical Psychology, *by Michael Fordham. New York, N.Y., John Wiley & Sons, 1978, 175 pp., no price listed.*

This is the first in a series of books edited by Prof. Boris Semeonoff of Edinburgh University on methods in psychotherapy. The selection of Michael Fordham to present Jungian theory and method is a fortunate choice. Fordham is well known, articulate, and thoughtful. He has presented

Jungian thought extensively through the *Journal of Analytical Psychology* as well as in books and other writings. He is an editor of the Bollingen edition of Jung's collected works.

Jung, like Freud, lived a long and continuously productive life. His interests changed over the years, and the many organizations deriving from his thought have varied greatly in their emphasis. Dr. Fordham says that the London school has been brought "much nearer to psychoanalysis" and "in particular the Kleinian school . . . somewhat to the consternation of the more conservative members." Fordham's particular interest in the Kleinian school stems from his early career as a child psychiatrist and his observation that Jung was not especially interested and did not write much about the development of children, whereas Melanie Klein's career was built on her imaginative and creative ideas about childhood.

The first section of the book is devoted to a condensed exposition of Jung's theories. The rest describes Dr. Fordham's own modifications of traditional Jungian methods, his underlying theory, and his technique. Traditional analytical psychologists stress the processes of amplification and education with extensive development of mythological and historical themes, rather than the more specific analysis of the patient's personal unconscious, past experience, current problems, and current symptoms. A long-time criticism of Jung's method is that it does not deal effectively with aggression. Fordham recounts one tale in which Jung dramatically suppressed aggression and commented that then the analysis could proceed. Fordham sets limits to the amount of physical interaction and acting-out that he allows—more than Jung would tolerate. Fordham's description of a patient's behavior (painting his face and neck red, biting him) would not be acceptable to some analytical psychologists.

Fordham also does not like the recording of dreams, a characteristic tool of Jungians. He feels that by the time they get to the analytic hour dreams may be cold, and the patient may be in quite a different place psychologically. Furthermore, he discounts the usefulness of Jung's widely used typology as a therapeutic tool. He grants the typology a place in theory and research but believes that it is not as fixed as many Jungians think and may thus be misleading in its explication of human interaction.

In the last two-thirds of the book Fordham describes his own techniques and methods and the theory behind them, contrasting his approach with Jung's. Fordham stresses regression, transference, and countertransference more than is usual in Jungian writings. Traditionally, the Jungian analyst sits facing the patient. In an atmosphere of shared dialectic two people seek an answer. It was Jung's practice to see patients not more often than twice a week—often less—except in times of crisis. He took long, previously announced vacations and expected his patients to do the same. He frequently recommended places for them to go and hoped they would enjoy themselves, as he expected to.

Clearly, Jung's patients were not as sick as Fordham's. Jung was frankly afraid of "latent psychosis" and would terminate analysis if he smelled one in the offing. Many of his patients were in the second half of life, were intellectual, had had reasonable success, and had intact egos. Many were in mid-life crisis, and depression was a leading feature. Fordham, on the other hand, treats patients with character disorders and a "selected number of psychoses." He sees them three, four, or more times a week, and he uses the couch. In contrast to Jung's attitude toward vacations, Fordham fears that taking long weekends or holidays may cause his patients to fall apart.

Fordham discusses regression, transference, countertransference, and interpretation. He discusses the transference neurosis, a term not used by Jungians, and the importance of its resolution. He recognizes and discusses the archetypal elements in transference. Jung was not much concerned with resolution and interpretation of the transference, except when it was interfering with analysis, as in the case of the "inflated transference." Jung's patients were not as dependent or as regressed as Fordham's, and he felt generally that the transference would take care of itself and was not doing any harm anyway. In fact, he thought the transference might build a bridge to another relationship. In line with these differences, Fordham underplays symbol formation and its use in individuation and the amplifcation education technique in general. He says that placing stress here emphasizes the analyst's interest and ignores the resolution of the patient's conflicts in the transference neurosis. He tends "to replace them with a kind of religion in which the study of symbolic material takes first place."

Parts of this book have been published elsewhere, and thus there is a certain amount of repetition. The book constitutes a useful and clearly stated exposition of the position, theory, and practice of a well-known and experienced analyst of the London school.

MARGARET C.-L. GILDEA, M.D.
Woods Hole, Mass.

To Be an Invalid: The Illness of Charles Darwin, *by Ralph Colp, Jr., M.D. Chicago, Ill., University of Chicago Press, 1977, 276 pp., $17.50.*

Charles Darwin's chronic and disabling illness has perplexed a succession of scholars, beginning with the great evolutionist himself, who at the age of 16 started to observe his own symptoms while practicing medicine under his father's supervision. The elder Dr. Darwin for many years advised and treated his ailing son for a host of complaints, including abdominal distress, gaseous vomiting, skin eruptions, anxiety, and depression. During his voyage on the *Beagle* Darwin was often severely seasick, and later he often became ill as a result of "thinking evolutionary thoughts," experiencing "mental pain . . . when he searched for a plausible cause for evolution."

Darwin feared that marriage would interfere with his work, and he dreaded pregnancies (but he married his cousin Emma, a devoted and caretaking woman who bore him 10 children). By the age of 33 Darwin was so debilitated that he could only take short walks, and he moved to the country hoping to improve his health. After his father died, he transferred his medical dependence to Dr. James Gully, who started him on a lengthy hydrotherapeutic regimen. He later leaned heavily on a number of quite prominent British physicians, including Queen Victoria's personal doctor, Sir William Jenner.

Only during his middle years was Darwin able to write the books that made him famous. Worried about the hostility his evolutionary theories might evoke from religious leaders, he developed what Dr. Colp describes as a "severely negative and masochistic identity." Darwin tolerated criticism poorly, noted himself to be "burning with indignation" when disagreed with, and became seriously depressed during his 50s. But as he gained recognition in his 60s there was a gradual improvement in health, and he died rather peacefully at the age of 73 of coronary artery disease.

Dr. Colp's masterful analysis of Darwin's invalidism is divided into two sections. The first is a detailed description of all his various symptoms and treatments, and the second is a dispassionate review of the many theories that have been proposed to explain the illness. These include possible metabolic diseases (gout, hypoglycemia, porphyria), infections (Chagas' disease, malaria, amebiasis), anatomic problems (hiatus hernia, eye-strain), toxicity (arsenic poisoning, allergy to pigeons), and psychological factors (overwork, unconscious hostility toward his father, bereavement). Curiously, Dr. Colp, a psychiatrist, says nothing about Darwin's childhood development (the history begins when Darwin is in his teens), nor does he comment on the fact that no data are available about Darwin's sexual life. Nearly half of the book is devoted to Dr. Colp's sources of information, including the extensive memoranda kept by Darwin and his family about illnesses and medications. Darwin carried on a lifelong, probably psychotherapeutic correspondence with his best friend, Dr. Joseph Hooker, and Colp relies heavily on these letters.

The book is extremely well organized, with copious footnotes, and should serve as an antidote to some of the more speculative "psychobiologies" (1) that lately have been published about famous people. Indeed, Dr. Colp's intellectual honesty reminds one of Darwin's own scientific style, in that he comes to the modest conclusion that "it may be impossible to ever be certain about the causation of his illness." Nevertheless, Colp believes that "psychological stresses were the most probable cause."

This book can be recommended not only for its scholarship but also for the basic message that great suffering is not incompatible with extraordinary achievement. Taking issue with Sir George Pickering's view of Darwin's illness as a desirable part of Darwin's creativity (2), Dr. Colp finds that Darwin was creative in spite of his illness, not because of it.

Hypnosis at Its Bicentennial: Selected Papers, *edited by Fred H. Frankel, M.B.Ch.B., D.P.M., and Harold S. Zamansky, Ph.D. New York, N.Y., Plenum Press, 1978, 301 pp., $27.50.*

These papers were presented during the Seventh International Congress of Hypnosis and Psychosomatic Medicine in Philadelphia in 1976. About 600 medical hypnotists from 19 countries shared their ideas; from among these, only 29 contributions have been selected for publication in this book. *Hypnosis at Its Bicentennial* represents the best possible introduction to the variety of interests, theories, methodologies, and practices of modern hypnosis. The book has been scrupulously edited by an astute clinician, Fred Frankel, and an enlightened experimental psychologist, Harold Zamansky. It contains E.R. Hilgard's latest comprehensive concept, neodissociation, and K.S. Bowers' superb theoretical formulations of absorption and dissociation. There are sections on the history and theory of hypnosis, experimental thought and methodology, and clinical studies on the efficacy of hypnosis in treating migraine, on a burn unit, and in alleviating problems in cancer, anxiety, asthma, sexual dysfunction, pain, airplane phobia, and multiple personality.

In "What Did He (Bernheim) Say?" A.M. Weitzenhoffer clarifies Bernheim's often-quoted statement, "There is no hypnosis only suggestion," by emphasizing that Bernheim had also pointed out that hypnosis was a "suggestion state" and a specific "condition of enhanced suggestibility."

J. Knox and associates discuss "Hypnotic Analgesia vs. Acupuncture in High and Low Hypnotically Susceptible Subjects" and state that not only was hypnotic analgesia more effective than acupuncture in reducing pain but 4 out of 12 highly susceptible subjects reported virtual elimination of cold pressor pain while under hypnosis. They conclude that "the relationship between hypnotic susceptibility and response to acupuncture is at best weak." The problem of whether hypnosis is actually a psychophysiological state is discussed by V.E. Rozhnov of Russia, whose data indicate that "when the subject enters a deep stage of somnambulism, there occurs a shift of consciousness with accompanying changes in the decasecond rhythm of the brain's bioelectric activity. These decasecond rhythms . . . are related tc hypnotic suggestions." J.C. Ruch's paper on "Self Hypnosis with Implications for Other Self Control Procedures" includes the statement that "self hypnosis is as effective on both objective and subjective measures as heterohypnosis in an *experimental* situation."

E. Dengrove and A. Lazarus, writing on the topic of hypnosis and behavioral therapy, agree that these techniques can be combined to great advantage. D. Ewin's "Clinical Use of Hypnosis for Attenuation of Burn Depth" indicates that hypnosis may be a significant factor in rapid healing and resistance to infection.

For special commendation I would select the papers of D.R. Collinson of Australia on asthma and by J.H. Hilgard and A.H. Morgan on "The Treatment of Anxiety and Pain in Childhood Cancer Through Hypnosis."

An adequate index is provided. I highly recommend *Hypnosis at Its Bicentennial* to anyone who is interested in knowing more about the theoretical concepts, research aspects, and practical interests of modern hypnosis.

JACOB H. CONN, M.D.
Baltimore, Md.

Psychoanalysis, Creativity, and Literature: A French-American Inquiry, *edited by Alan Roland. New York, N.Y., Columbia University Press, 1978, 355 pp., $20.00.*

Surprisingly enough this symposium-produced book is aptly titled and smoothly written. It bears the mark of an expert editorial hand, and Roland's introduction nicely sets the scene. The translations are excellent, avoiding what Aring once called the sense of grazing on a tether.

The three indexes include "Literary Works," with 28 references, and "Subject Index," with 19 references to "desire" and 13 references to poetic matters. Perhaps this is the French influence; certainly French psychoanalysis has become closely associated with philosophy, linguistics, literature, and structural anthropology. American psychoanalysis is also tied to the humanities, and one of the four sections of the book is all-American: the section on creativity, in which we are treated to Albert Rothenberg's groundbreaking creativity research.

This book is a particular pleasure for a reviewer because it has so much on words, language, and writing. André Green tells us of the power of writing to promote affects, a power so great that we sometimes prefer the affects generated by writing to those of life. He says language has pressure and that words, sentences, and style have irradiation and recoil effects. Green sees the writer standing on the fringes of the crowd, unnoticed, keeping to himself, forgetting and forgotten, inscribing a sign on a surface for someone absent.

We meet the unique and typically French phenomenon, Jacques Lacan, a man with the secret of arousing people and passion and a person of such influence that French psychoanalysis has been accused of becoming populated by "little Lacanians." Lacanian concerns are the relation of the unconscious and linguistic structure, "listening without knowing" (approaching the patient's associations without preconceived categories), and the need to be in touch with the patient's unconscious desire. The concern of others is Lacan's five-minute analytic sessions.

In the section on sociological perspectives, psychoanalysis in France is described as having become a fashion—one in which the image of the analyst as *barbu avec lunettes* has changed so that those on the Left are the most rather than the least favorably disposed to it.

In the section on psychoanalysis proper, we are told that what is being played out in the unconscious is the life of desire, with each part of our bodies speaking in the forgotten language of love. The problem is, as the actor says in Bergman's *Scenes from a Marriage,* "We are illiterates when it comes to love."

In a paper on "The Disconnected Self" we are reminded that the psychoneurotic patient of Freud's time has almost disappeared from the consulting room. Patients come today because they are no longer willing or able to bear their crumbling self-esteem. We see the narcissistic personality disorders, and the term "alienation" is used for the malaise of our time, replacing the banal use of "neurotic."

The section on creativity echoes Owen Barfield, noting that words are signs of natural facts and that each is borrowed from something material, something appreciated by one of the five senses, in particular the sense of touch or feeling. The self selects key words and they shape further developments of the self.

In this section Rothenberg spells out first his "Janusian thinking": the simultaneous conception of opposite, contradictory ideas or images (i.e., symmetry) and, second, his "homospatial thinking": the conceiving of two or more discrete entities occupying the same space (i.e., unity). He tells us that the homospatial conception leads to integration, an essential feature of metaphor. He notes that metaphors occupy a central place in the creations of painters, writers, sculptors, architects, and other types of artists, as well as applied and theoretical scientists. Since neither the artist nor the scientist is aware of the structure of the thinking, ideas seem to come out of the blue, but the creator is not suffering from divine madness. He or she is a more sensitive and flexible thinker capable of using and blending modes of thought in unusual ways.

Another essay on creativity notes that the artist must wrest his or her uniqueness from the collectivity in which he finds himself, yet create a product in harmony with the culture. As Otto Rank pointed out, the artist must appoint himself as an artist. The experience of the therapist's belief in and respect for individuality creates the atmosphere of trust in which arises the will to change and create.

In a work on creation of plays—or any piece of writing, for that matter—it is hypothesized first that the play deals at some level of consciousness with the writer's feelings about his own creativity and, second, that in every play the cast of characters represents a projection of elements of the playwright's identity. It is suggested that study of an author's plays will consistently reveal an internal gallery of characters from his past.

The section on psychoanalysis and literature contains a piece on the third face of psychoanalysis: what is "out there" and its relation to what is "in here." This is the world of the self versus nonself, and "identity" is the key term. We read one another like music, hearing ourselves play our lives like variations on a melody, yet, as Freud said, our egos lose their boundaries when we fall in love or have other mystical experiences. This may happen when we become "absorbed" in literary or artistic works.

Another paper reviews ways psychoanalysts have explored literature. First was the elucidation of the universality of unconscious fantasies from psychosexual stages of development. Second was investigation of the unconscious motivation or psychopathology of a character. Third was relation of the hidden psychological meanings in a work of art to the author's life, e.g., Freud's work on Leonardo da Vinci and Kligerman's study of Pirandello and his *Six Characters in Search of an Author.*

An essay on narcissism quotes Proust on how people in love seek themselves in the objects of their desire. They endow the desired object with mystery and beauty that really flow from themselves. The self radiates enough energy to transfigure commonplace reality into its own image and turn it into poetry. Everybody believes that someone else possesses the self he wants to acquire; this is why everyone experiences desire.

A final note states that every successful cure implies integration of the subject's psychic bisexuality; inversely, every serious threat to sexual identity or integrity is likely to lead to a variety of disturbances to the point of psychosis. Belonging to a sex, it is said, constitutes one of the firmest kernels of personality coherence.

This book is well written, well translated, and wise. It is also entertaining, and the various "Literary Works" constitute a tasty, easily digestible mélange. It is recommended for psychiatrists as well as those readers interested in creativity and literature—the lovers of the Word.

MORGAN MARTIN, M.D.
Medical Lake, Wash.

The Painted Message, *by Otto Billig and B.G. Burton-Bradley. Cambridge, Mass., Schenkman Publishing Co. (New York, N.Y., Halsted Press, John Wiley & Sons, distributor), 1978, 255 pp., $19.50.*

This book breaks new ground in anthropology, psychiatry, and "creativity" as reflected in the mentally disturbed patient. It takes a comprehensive and multidisciplinary approach that is original. It enables the reader to find entrance into the distorted world of the schizophrenic patient through the "painted message."

The "chronicity" of the schizophrenic patient originates, for the most part, from an inability of the therapist to establish, stimulate, and enhance nonverbal communication when verbal channels are blocked, disturbed, or meaningless. This is the principal idea of the book; it is well documented and exemplified by the clinical cases and the "paintings" of the

patients. The text is leavened by clinical cases, which skillfully complement the theory.

The authors focus on dynamic and developmental approaches in chapters titled "The Stage Is Set," "Creativity and Psychotic Disintegration," "Schizophrenic Expression and Western Art," and "Magical Thinking." They endorse the theory that the schizophrenic process is a regression to early stages of development in all functions of the mind, including communication and creativity. Therefore, the "art" of the schizophrenic patient shows and is typefied by fusion of ego boundaries, lack of self-differentiation, and disturbances in dealing with external and internal space. Furthermore, the paintings of schizophrenic patients are characterized by transparency, lack of or mixing of perspective (vertical, horizontal, and diagonal), presence of a "base line," *perspective tordue,* absence of "geschtalt," amoeboid and amorphic elements, and appearance of primordial universal symbols when the conventional ones have lost their meaning.

The symbolic language of the painting, like dreams, has to be understood and interpreted by the therapist to uncover the latent meaning obscured by the manifest one. This is based on the great similarity between spontaneous painting and dreaming. Furthermore, the authors argue—justifiably, in my opinion—that the painting has properties that are therapeutic and reconstructive and not only cathartic, as is usually presumed.

The chapters on "The Conception of Space" and "The Structure of Space" deal with the patient's perception of space. Looming in the background of the authors' comments are philosophical, historical, and biopsychosocial aspects of space. Their discussion of space pathology is a major contribution in this field. In some cases the pathology of space indicates the patient's relationship to external objects (object relationship), his or her sociability and integration with society, and his or her perception of the body image and the self and external world (depersonalization and derealization).

The chapters "Crosscultural Diagnosis in Psychiatry," "New Guinea and Its People," "Societal Significance of Tribal Art," and "Schizophrenic Expression and New Guinea Art" stress the universality of the basic psychopathology of the schizophrenic process and its creative expressions. At the same time the authors do not lose sight of the diversity and social-cultural-ethnic determination of secondary signs and symptomatology, or of their elaboration and expression. It is generally accepted, as the authors state, that "the regression to common universal patterns in severely disintegrated patients, regardless of cultural backgrounds, suggests a common basis for the development of personality structure and space concepts."

The book includes an ample appendix, a glossary of technical terms for nonprofessional readers, and extensive and suggestive references that are most useful for the casual as well as the professional reader. However, details are overabundant and at times repetitious.

Some of the issues raised in the book remain controversial and deserve further study and consideration; e.g., the differences between modern, primitive, tribal, and prehistoric art and "psychotic art" or artistry of the mentally ill. Another issue left unresolved is the impact of mental illness on the creativity of the artist. It is not at all obvious that creativity deteriorates after mental illness. Some changes do occur, but they are not always detrimental.

I strongly recommend this book to all who deal with mental health, creativity, art (history, theory, and critique), and education as a very important source of knowledge, experience, and guidance in their everyday practice.

MARCEL ASSAEL, M.D.
Rechovot, Israel

Psychopharmacology of Thiothixene, *by Thomas A. Ban, M.D. New York, N.Y., Raven Press, 1978, 236 pp., $12.50.*

Rather than review a category of psychotropic agents, the author has chosen to study one of the thiozanthene series in depth. His review of thiothixene is both thorough and exhaustive.

The book is organized so that the first eight chapters discuss basic topics such as the history, synthesis, metabolism, biochemistry, physiology, and pharmacology of the drug. The next three chapters deal with clinical use, including indications for administration, side effects, and comparison with inactive placebo and other drugs that have established therapeutic indications. Thus, it is possible for the clinician to ignore the first part of the book if he or she wishes and to obtain helpful data regarding clinical applications of the drug. On the other hand, those who wish to learn more about thiothixene will find everything they need to know in the earlier chapters. There is also an excellent bibliography at the end of the book.

There are many tables in this book, some of which are so detailed that they obfuscate rather than clarify. Nevertheless, this form of in-depth careful analysis of a single drug could become a model for future dissemination of information about psychotropic agents. One might legitimately question, however, whether thiothixene is of sufficient importance in relation to other psychotropic agents to merit this degree of detailed scholarship.

SIDNEY MALITZ, M.D.
New York, N.Y.

Effective Ingredients of Successful Psychotherapy, *by Jerome D. Frank, Rudolf Hoehn-Saric, Stanley D. Imber, Bernard L. Liberman, and Anthony R. Stone. New York, N.Y., Brunner/Mazel, 1978, 212 pp., no price listed.*

The point of this book is that the effective ingredients of successful psychotherapy cut across all approaches and "schools" of treatment. In explicating the nature of this common denominator, Dr. Frank and his associates cite evidence from various medical specialties, including psychiatry, demonstrating the beneficial results when patients and therapists expect that the treatment will work. They quote Freud's assertion in 1905 (1) that "expectation . . . coloured by hope and faith . . . is an effective force with which we have to reckon . . . in *all* our attempts at treatment and cure."

This point is already part of the folk wisdom of psychotherapy for practitioners and researchers alike—in no small part the result of the widely published work of Frank and his group. Their work may be in the third phase of the evolution of a theory as William James is reputed to have described it: after first being attacked as absurd, then regarded as true but obvious and insignificant, it finally has reached the stage where it is regarded as so important that its adversaries claim it as their own.

In chapter seven, which "contains the authors' combined

reflections," they become more specific about the mode by which these expectations operate. They take the position that a broad range of symptoms, which may be either "exaggerations of commonly experienced states" or the traditional phobias and obsessions, are best viewed either as manifestations of "demoralization, or as self-defeating strategies to combat [demoralization] by eliciting supportive responses from important others." Their view is that "whatever their origin, symptoms can contribute to the patient's demoralization by diminishing coping capacity." Thus, they conclude that the "effectiveness of all forms of psychotherapy largely depends on their ability to restore morale through combating destructive emotions . . . and foster health-promoting ones. . . . This is also achieved by enhancing the patient's sense of mastery or control over himself and thereby [over] his environment."

The assumptions in this position are made explicit on page 171: "The thesis that emerges from our studies is that, although both patients and therapists assume that the patients come to psychotherapy primarily for relief of specific symptoms, the chief reason they do so is that they are demoralized." Demoralization is defined operationally by the authors as the perception of patients themselves, as well as by others, that they have failed to cope with some aspect of life through their own inadequacies. I might sharpen this definition on the basis of research carried out with Tobin (2, 3) by pointing out that shame at the inability to cope (which to us seems synonymous with feeling demoralized) is often heightened by the need for help from another person. Thus, we would see demoralization as an inevitable subjective emotional state occurring as a consequence of whatever "symptom" the patient seeks relief for. Frank and associates' phrase "combating destructive emotions" is really a metaphor for the rise in the patient's self-esteem when previously unacceptable emotions are expressed in the presence of an approving authority figure and found acceptable (2, p. 596). Thus, the mechanism of action of the therapy they describe is the identification with the therapist, who either does not have the same problems the patient does or reacts to them differently.

In chapter four the problems of long-term follow-up investigations of psychotherapy are discussed. The authors are not optimistic about psychotherapy's long-term effects, although it does serve to shorten the duration of a patient's distress and disability. One problem in evaluating such findings, as Frank himself points out, is the way in which concern about the long-term effects of psychotherapy may erroneously derive from the traditional medical model of "five-year cure" (p. 124). Thus, someone with gall bladder disease whose offending organ has been removed will presumably be symptom-free of that disease at the end of five years, but the kind of psychotherapy studied by Frank's group is primarily oriented toward the restoration of a symptom-and-shame-free equilibrium. They are not able to measure the extent to which their treatment provides the patient with the "tools" to maintain that equilibrium or even to raise it to a higher level of integration. This problem is also addressed in chapter one (p. 20): "Practitioners of long-term therapy such as psychoanalysis find that their patients take months or years to respond," in contrast to behavior therapists, hypnotherapists, and others. This seems to be a misunderstanding of the fact that acute symptom relief (whatever distress the patient seeks relief for now) usually occurs early during psychoanalysis, but that chronic symptoms, due to chronic intrapsychic conflict and arrested or deviant development, do not disappear easily. Thus, it may be that a form of psychotherapy specifically organized to treat chronic symptoms (e.g., psychoanalysis) might provide better data for long-term follow-ups. It should be noted that the indications and criteria for psychoanalysis have been spelled out recently in a form that also requires the psychoanalytic diagnostician to justify the choice of psychoanalysis over briefer, less expensive forms of psychotherapy (4).

In my opinion chapter three presents a series of distortions based on an initially accurate description of the ambiguous nature of psychoanalytic treatment as the patient experiences it. I think the authors draw unwarranted inferences from their description about the supposedly coercive characteristics of psychoanalysis, but the reader can readily correct these by referring to our work (2).

Chapter six describes the natural history of the Johns Hopkins Psychotherapy Research Unit—a group with a productive output of published papers and a record of effectively treating hundreds of outpatients over the 27-year span up to 1974. Anyone who has ever participated in clinical research with colleagues can appreciate the deeper implications of how the "place in the authorship credits shifted from straight alphabetizing, to coin-flipping, to fair and open discussions of who should occupy which place." The emergence of the "task-oriented social unit" that grew out of this method is alluded to, but unfortunately there is no full description of the process. From my own experience it is clear that the clinical researchers' relationship to their patient-subjects and the data generated by that relationship is importantly affected by the researchers' relations with each other, a fact not always appreciated in clinical research. Thus, the search for truth and mastery through understanding the data of human transactions is always extremely difficult. In response to the emotional pain of this task, there is a tendency among colleagues to regress in their relations with each other. Then the viability of the research group may depend on the members' ability to provide each other with emotional as well as cognitive support based on mutual awareness of and ability to deal openly with their various feelings. In this way the task-oriented, secondary-process quality of the work can be maintained.

Brain Dysfunction in Aggressive Criminals, *by Russell R. Monroe. Lexington, Mass., Lexington Books (D.C. Heath and Co.), 1978, 211 pp., $17.95.*

Dr. Monroe has long been interested in the neurophysiological aspects of aggression. In a 1970 monograph, "Epi-

sodic Behavioral Disorders" (1), he proposed a classification system for aggressive and psychological variables. The current volume reports a prospective study to test his hypothesis on a group of individuals with known histories of uncontrolled aggression. Working with a prison population, a research team collected extensive neurological, psychological, demographic, and social data, which are presented at length. They further evaluated the effects of anticonvulsant medication over a short-range trial.

The researchers are to be commended for their scholarship and diligence in developing a classification system that supports Monroe's hypothesis. Of considerable interest is the high rate of brain dysfunction in the subject population (over 50%), even though dysfunction is defined rather broadly and includes many different diagnostic entities.

The significance of the work lies more in the implications of the specific findings than in the raw data. By attempting to establish a systematic approach to the study of aggression, the author demonstrates an unwillingness to accept a holistic approach to the subject. The study actually raises more questions than it answers, but it serves the function of stimulating further research. For instance, specific types of brain dysfunction need to be correlated to aggression, a better way of correcting dysfunctional elements needs to be developed, and dysfunction needs to be detected earlier to minimize psychosocial impairment.

For the casual reader, the book is often complex, technical, detailed, and not easily understood. Except for those who are actively engaged in similar research, it will probably have limited appeal. Nevertheless, the implications of this work are important, and I would encourage referral to several of Dr. Monroe's other publications on the subject.

A Systems Approach to Alcohol Treatment, *by Frederick B. Glaser, M.D., Stephanie W. Greenberg, M.A., and Morris Barrett, M.P.H. Toronto, Ont., Canada, Addiction Research Foundation, 1978, 303 pp., $14.95 (paper).*

This presentation is a report of a multidisciplinary study of the resources available for the treatment of alcoholism in Pennsylvania in the calendar year 1973. The undertaking was motivated by a growing concern over the increasing complexities and cost of such services and an attempt to apply criteria by which the structure and functioning of such programs could be judged. On the basis of their study the authors conclude,

> As lengthy as it is . . . . this book really tells a rather simple tale. A group of interested people wanted to find out what was being done in terms of the treatment of alcoholism in Pennsylvania. There, they visited all the programs which were performing this service. They saw much that was good, but they found that there was no overall coherence or unified thrust to the effort. It was fragmented, entrepreneurial, redundant, and discontinuous.

The basis of this assessment and the approaches to their evaluation of the resources are documented in the presentation by an orderly detailed outline of the various treatment programs, including the criteria by which these have been judged, the involvement of other agencies in these treatment programs, and a plethora of figures, charts, tables, and appendixes. However, the final judgment of the authors may be questioned. The challenge arises from the uncertainties concerning the relationship of treatment facilities to outcome of treatment, in view of the limitations of our current knowledge of the nature of alcoholism and its cure.

Despite this criticism of the judgment concerning the merits of the different programs, the authors have done an excellent service in providing an extensive survey of alcoholism programs in a systematic manner. Their report is well organized, divided into the four sections of Background, Organization, Criteria and Objectives, and Conclusions. There is also a selected bibliography. The report includes historical notes that add to its depth. The authors are careful to point out that programs studied in 1973 may have changed. Nevertheless, the data base they have provided and carefully formulated offers an excellent guideline for those individuals concerned with assessing the treatment resources employed in the prevention, containment, and treatment of alcoholism.

ALBERT A. KURLAND, M.D.
Baltimore, Md.

Drinking: Alcohol in American Society—Issues and Current Research, *edited by John A. Ewing, M.D., and Beatrice A. Rouse, M.Ed. Chicago, Ill., Nelson-Hall, 1978, 432 pp., $19.95; $8.95 (paper).*

This pleasant to read book is divided into five parts: Introduction and History, The Complications of Drinking, Psychosocial Aspects of Drinking, Social Policy and Drinking, and Summing Up. The chapters are written by 19 experts, many of whom are well known in the field of alcohology. The reader's interest is stimulated but not satisfied by this book. The discussion of medical complications of excessive drinking is inadequate. However, in the same section, the chapters by Ewing on social and psychiatric considerations of drinking are excellent, as is a provocative chapter titled "How Risky Is Drinking?"

An interesting study by Globetti on teen-age drinking in a rural high school in a dry Mississippi area is quite different from the usual urban studies. Globetti found less drinking, more guilt about it, and, for those who drank, more trouble related to drinking. Rouse and Ewing report on a 20-year follow-up study by Straus and Bacon of college drinkers that showed a drop in problem drinking by men from 42% to 17% but a rise in women from 11% to 12%.

A review of state alcohol control laws by Loeb leads him to the conclusion that wider legalization of liquor leads to greater per capita consumption, that government ownership of outlets reduces consumption, that more outlets mean more consumption, and that liquor-by-the-drink laws lead to greater consumption. The following chapter by Popham and associates makes the important argument that consumption is not distributed on a bimodal curve; i.e., alcoholics and other drinkers are not two groups: one is the continuation of the other. They believe this suggests a strategy that lower total consumption would reduce pathological drinking. One strategy they believe may have some merit is control of con-

sumption by pricing because data in Ontario and other places show that as the price of alcohol rises, consumption and death from cirrhosis drop.

These chapters are followed by a very insightful chapter by Room titled "Evaluating the Effect of Drinking Laws on Drinking." Room is not too impressed with Popham and associates' hypothesis, which, incidentally, has caused a great deal of public outcry from the "alcohol field" for fear it would suggest a return to a prohibitionist viewpoint. Room points out that, since 10% of the population drink 60% of the alcohol, changes in consumption rates and cirrhosis are naturally highly correlated because they are essentially the same thing. He discusses three theories about the possible effects of laws on drinking. The null hypothesis is that there is no relationship. The constant proportion theory is the one advanced by Popham and associates. The inoculation theory suggests we should teach healthy drinking from an early age. Room's chapter is the best of the book and is of great value to those involved with prevention strategies.

The book ends with a fine overview by Rouse and Ewing. An enticing little nugget they throw in is the finding that mice from a high-alcohol-consumption strain raised by mothers from a low-consumption strain drink half as much as their littermates raised by their natural mothers; mice from a low-consumption strain drink twice as much as their littermates raised by their natural mothers. The implications for genetic research of this observation are obvious.

This book has a number of good things in it for those trying to make sense out of this complex field; and this fact outweighs the weak chapters and the imbalance of space given to some subject matter.

ROBERT A. MOORE, M.D.
San Diego, Calif.

The Prevention of Sexual Disorders: Issues and Approaches, *edited by C. Brandon Qualls, John P. Wincze, and David H. Barlow. New York, N.Y., Plenum Press, 1978, 196 pp., $14.95.*

This book contains an interesting and provocative collection of papers that the editors have attempted to unify around a central theme of prevention. In the introductory chapter Dr. Qualls makes a careful effort to provide a background for thinking about these issues. He provides abundant evidence for the importance of approaching sexuality from a preventive perspective. In many of the chapters, however, prevention appears to be an afterthought, or even a contrivance. The problems of prevention are complex, and, as presented, they are often not well formulated or directly applicable to the specific chapter content.

The topics covered in this volume represent a wide range of interesting and important areas, including the role of cultural values, the child with cross-sex identity, sexual offenses, and the role of antiandrogens in the treatment of sex offenders. There is also some discussion of sex education, the role of pornography, and ethical issues. Some of the chapters are excellent and cover the material in a consolidated and thoughtful fashion; others sound more like unedited presentations from a symposium, thus detracting from the generally serious and well-modulated tone of the book. The final chapter, by R. Kolodney on ethical issues, provides a well-integrated view of the complexity of the problems faced in this field and would make an excellent stimulus for discussion. Although its flaws make the book less useful as a text, it can be recommended as a supplement to course material. The book is generally good reading and evokes critical thinking.

CAROL C. NADELSON, M.D.
Boston, Mass.

Progress in Sexology: Selected Papers from the Proceedings of the 1976 International Congress of Sexology, *edited by Robert Gemme and Connie Christine Wheeler. New York, N.Y., Plenum Press, 1978, 593 pp., $32.50.*

This book consists of 113 papers representing the work of about 200 authors. It is divided into sections covering Sexual Differentiation and Dimorphism; Sexual Dysfunction; Sexual Response and Fantasy; Fertility, Infertility, Contraception; Anthropological and Sociological Studies; and Sex Education. It undoubtedly represents an enormous amount of work on the part of the editors. To get papers from so many authors and from such a diversity of points of view and countries of origin is a labor that cannot be underestimated. However, from the reader's point of view it is to little avail.

Most of the authors have inadequate space to develop their ideas in sufficient depth to make the book a good reference source. Some of the authors have been widely published and their work is therefore readily accessible. For instance, in his chapter on "Hormones and Sexual Behavior" Gunter Dorner cites himself 22 times. Other authors have little to say worth publishing. The fluctuations in style make the book a poor one to serve as an introduction to the general area of concern of "sexologists."

I think the editors deserve a great deal of praise for putting this book together and for the complicated obstacles they must have had to overcome to do this. However, I see no reason why anyone would want to buy or read the book.

HARVEY BLUESTONE, M.D.
Bronx, N.Y.

Human Growth and Development: Wolfson College Lectures 1978, *edited by Jerome S. Bruner and Alison Garton. New York, N.Y., Clarendon Press (Oxford University Press), 1978, 167 pp., $10.50; $5.50 (paper).*

This small volume is a collection of six lectures given at Wolfson College, University of Oxford, in 1976. Other than the common theme of early child development, there is no particular relationship among the subjects of the lectures. Therefore, I will mention the titles of the chapters to inform the reader of the varied contents. The first, "Social Development: A Biological Approach" by Prof. Robert Hinde, deals with issues that arose from the study of nonhuman primates and focuses primarily on mother-infant relationships. This is somewhat related to the second, by Dr. Michael Rutter, titled "Early Sources of Security and Competence." The latter addresses some of the same questions as they relate to human children and the social stresses that put them at risk. Rutter also discusses the ameliorating influences that allow children at risk to achieve emotional security and social competence.

The next two lectures have in common the topic of language acquisition. In "Learning How to Do Things with Words", Bruner stresses how the young child learns to use

language in the context of social living. He builds on the mother-child interaction from the earliest nonverbal communications, describing how higher-level verbal language develops out of the interaction. Perhaps because this was a lecture on words, I was struck with the author's extraordinarily long and complex sentences. The following chapter, "From Gesture to Word," is a discussion by Clark of language development as it relates to and depends on cognitive development. These two chapters are for students of linguistics.

In the fifth lecture, "New Currents in Genetic Epistemology and Developmental Psychology," Inhelder reviews some of Piaget's theories and discusses further work on cognitive development that is being done by the Geneva group. The final chapter, "Nursery Needs and Choices," is a more pragmatic discussion. Tizard comments on the history of nursery services, parental desires, controversies, and economic aspects of nursery services, as well as the well-being of children and of parents. He offers some practical recommendations on how services could be organized. This paper might interest a different group of readers than would the preceding papers.

Each of these lectures will appeal to a small group of highly specialized professionals; not necessarily the same group will be motivated to study each one. Those with a particular interest in early child development will find some common interests in all of them. Although it is a carefully written and informative book, it will not have much general appeal to the readership of the *Journal*.

JOSEPH M. GREEN, M.D.

Marriage and Marital Therapy: Psychoanalytic, Behavioral and Systems Theory Perspectives, *edited by Thomas J. Paolino, Jr., M.D., and Barbara S. McCrady, Ph.D. New York, N.Y., Brunner/Mazel, 1978, 566 pp., $25.00.*

This book not only illuminates the field of marital therapy as it is currently practiced but is a valuable contribution to the field of psychotherapy in general. Marital therapy does not have a single theory and practice that is idiosyncratic for marital therapists. Therapists enter the marital therapy field after having been trained in various disciplines and in other forms of psychotherapy—usually individual therapy. They bring with them the theory and practice in which they have been trained and apply it to the treatment of marital couples. Thus, the current three dominant theoretical perspectives of psychotherapy in general (psychoanalysis, behavioral therapy, and systems theory) have become the dominant theoretical perspectives in the area of marital therapy. Clinical practice of marital therapy clarifies, refines, and develops these theoretical perspectives so that they become more meaningful to practitioners of individual, group, and family therapy.

This book serves the valuable function of clearly picturing the current status of these three very different theoretical perspectives and their applications in marital therapy. The editors have done a great service in gathering together outstanding theorists and clinicians to present their views in original, updated contributions. The effective clarifications of the theorists and clinicians help clinicians gather their data and plan their interventions in a scientifically effective manner. Thus, a chapter on a particular theoretical approach is followed by a chapter on its clinical application. It can be observed in the theoretical chapters that despite the author's personal preference, there is no one agreed on psychoanalytic, behavioral, or systems theory. There are differences in theory in each of the three theoretical approaches, and an attempt to integrate all three into one theory of human functioning lies far in the future.

One of the principal goals of the editors was to provide the reader with a choice of models that can be used alone or in combination with other perspectives so that the student, researcher, or clinician can better organize his or her observations. Thus, the editors espouse an eclectic approach in the finest sense of the term. Indeed, this is what happens in practice as one can observe in reading the clinical chapters. What is done in treatment often violates the attempted purity of the preceding theoretical chapter. This is understandable, since clinicians, who offer service and who are primarily caretakers, do what will help the patient improve even if it violates the purity of a particular theory.

The book consists of nine chapters by leaders in the areas in which they are writing. It opens with a chapter by James and Janice Prochaska, which serves as a backdrop for the theorists and therapists who follow. William Meissner then offers the first theoretical chapter on the conceptualization of marriage and family dynamics from a psychoanalytic perspective.

In the third chapter Carol Nadelson shows how a psychoanalytic marital therapist can remain sensitive to important transference issues without being unduly restricted in the therapeutic modalities that can be applied. Nadelson is to be applauded in that she allows the couples' particular problems and needs to dictate the form that therapy will take rather than having rigid theories restrict its format.

In chapter four Robert Weiss presents the conceptualization of marriage from a behavioral perspective and shows how the union of marriage and behaviorism is not as unlikely as it has been considered. The clinical chapter that follows Weiss's theoretical one is by K. Daniel O'Leary and Hillary Turkewitz, who focus on the treatment of marital disorders from a behavioral perspective. They report their recent research on comparing communications training and behavior change contracts to determine which approach is most effective in helping marital couples.

The systems theory approach is covered in a chapter by Peter Steinglass on the conceptualization of marriage from a systems theory perspective and a chapter by Carlos Sluzki on a treatment approach from a systems theory perspective. Recognition should be given to the fact that systems theory and therapy are the most challenging contributions that marital and family therapy have made to the mental health disciplines.

Neil S. Jacobson presents a review of the research of the effectiveness of marital therapy. This is a very important chapter because marital therapy will remain in a state of confusion and disorganization until valid research studies prove the effectiveness of the many techniques in the field.

The final chapter, "Contemporary Marital Therapies: A Critique and Comparative Analysis of Psychoanalytic, Behavioral and Systems Theory Approaches" by Alan Gurman, is worth the price of the book. He attempts a systematic comparative analysis of the three theoretical perspectives. Integration of any one of these three fields has not yet been achieved, so that integration of all three is in our present state of knowledge an insurmountable task, but we should continue to make such valiant efforts toward a future integrative theory of psychotherapy in general.

OFFICIAL ACTIONS

Position Statement: A Call to Action for the Chronic Mental Patient

This statement was approved by the Assembly at its October 1978 meeting and by the Board of Trustees at its December 1978 meeting upon recommendation of the Ad Hoc Committee on the Chronic Mental Patient. It was prepared by the Ad Hoc Committee on the Chronic Mental Patient.[1]

THERE IS no more urgent concern than the needs of the chronic mentally ill who suffer from severe, persistent, or recurrent mental illnesses with residual social and vocational disabilities. As a result of the deinstitutionalization programs of the past decade and the continuing growth of high-risk populations that generate chronic illness, the problems associated with the care of these patients constitute a national crisis. The Conference on the Chronic Mental Patient, sponsored by the American Psychiatric Association in collaboration with the President's Commission on Mental Health, was held in Washington, D.C., January 11–14, 1978, and addressed the striking inadequacy of care, treatment, and rehabilitation of this group, estimated to number over one million Americans.

The chronic mentally ill are of all ages, including children, and have a variety of diagnoses.[2] They may reside in community or institutional settings. Such patients must be distinguished from those individuals who may be receiving various forms of psychotherapy for mental disorders without attendant long-term disabilities. The chronically ill have a host of special and unique problems including extreme dependency needs, high vulnerability to stress, and difficulty coping with the demands of everyday living, resulting in difficulty securing adequate income and housing and holding down a job.

The term "chronic mentally ill patient" stigmatizes persons so designated and obscures their diversity and potential for improvement. It is not a desirable appellation because of its implication of hopelessness and progressive deterioration but has been used in this report because of its historical and current use in the literature and by the profession and because of its descriptive clarity. While these people have a chronic illness that requires medical and psychiatric attention over a long period of time and are, therefore, appropriately called patients, it is equally important to recognize them as persons with continuing disability. This disability concept carries the positive implication that a psychosocial rehabilitation approach should complement any treatment provided.

Successful programs for helping the chronically ill patient offer a continuum of residential and nonresidential services to ensure that care is tailored to meet individual needs and to provide easy access and reentry to services and responsiveness to crises. Such programs use the skills of persons with an interest in and knowledge about chronic mentally ill patients. They provide thorough monitoring and balance active outreach with the encouragement of self-sufficiency and independence. They also encourage interagency cooperation and referral and serve as patient advocates. They have effective vertical (e.g., up higher governmental levels) and horizontal (e.g., across to other community agencies) structures. Sensitivity to incremental degrees of progress, economic stability, accountability, and responsibility are also essential features of effective programs.

Obstacles to effective delivery of services to the chronically mentally ill are monumental. They include the attitudes of patients, families, communities, community leaders, and professionals; the lack of an integrated community support system; fragmentation of federal programs; the absence of unified funding; the failure to designate responsibility for treatment, care, and rehabilitation of the chronically ill patient; widespread discrimination in employment, ambulatory care funding, zoning, etc.; and conflicting and/or limiting federal and state regulations.

POLICY STATEMENT

To address the needs of the chronic mentally ill, a national public policy must be adopted. This policy must include the following:

1. *Public sensitivity and financial commitment to a system of opportunities and services.* A systematic approach to caring for the chronic mentally ill must include at a minimum active case-finding and outreach; 24-hour emergency and crisis stabilization services; functional evaluation; medical and psychiatric care; training in skills of everyday living; so-

[1]The Ad Hoc Committee on the Chronic Mental Patient included John A. Talbott, M.D., chairperson, James T. Barter, M.D., Maurice Laufer, M.D. (deceased), W. Walter Menninger, M.D., Arthur T. Meyerson, M.D., Mildred Mitchell-Bateman, M.D., Lucy Ozarin, M.D., John P. Spiegel, M.D., and Harold Visotsky; Dr. Richard Duke, Dr. Z. Erik Farag, Dr. Henry Foley, Dr. Eli Ginzberg, Dr. Sam Keith, Dr. David Mechanic, Ms. Judith Turner, and Ms. Jane Yohalem were consultants, and Donald Hammersley, M.D., and Sam Muszynski, M.S.W., represented APA staff.

[2]In this report, the population we are concerned with are primarily those suffering from major psychoses, e.g., chronic schizophrenia, chronic recurrent affective disorders, etc. For reasons of simplicity and expeditiousness, the term, as used in this report, does not include persons suffering from alcoholism or drug abuse or the mentally retarded.

cialization; an array of specialized living arrangements; subsistence, prevocational evaluation, clinical work adjustment programs, and subsidized transitional and permanent full- and part-time work opportunities that are meaningful and feasible; and assistance to families—all of which are monitored and managed in accordance with individual needs. In addition, provision should be made for indirect services such as community consultation, community education, community organization, and interagency collaboration. The system should recognize that some patients, while chronically disabled, are only partially disabled and can function in supportive situations. The system should be designed to promote growth and sustain functioning to the maximum degree feasible for each individual and should be directed toward patients who voluntarily request assistance.

2. *Designation of clear responsibility for providing services at appropriate levels of government.* The assurance of care, treatment, and rehabilitation of the chronically mentally ill is a national public health responsibility. Thus, every level of government bears some responsibility to assure adequate services to this population.

The federal government should have the responsibility for defining eligibility; identifying and assuring levels of benefits; funding services under national health insurance or categorical programs; establishing regulations ensuring access to services, quality care, and cost effectiveness; and monitoring program implementation. The state government should assume responsibility for statewide planning, approval of local plans consistent with that statewide plan, supplementary funding and benefits, standards, and program monitoring within the state. At the local level, appropriate organizational entities should be responsible for local planning and integration of services for the chronic mental patient, administering and/or managing those services either directly or by contract, and evaluating programs.

3. *Full civil rights for the chronically mentally ill.* There should be no discrimination against the mentally ill. The right to adequate treatment in the community and to confidentiality must be guaranteed. Chronic mentally ill patients should have full access to medical, legal, educational, vocational, occupational, and housing services and opportunities. These services and opportunities to the mentally ill should be provided in settings that allow the maximum independence consistent with the patient's needs.

4. *Reform of funding mechanisms.* These should be designed to remove incentives toward more restrictive forms of care, to remove discrimination against the chronically mentally ill, and to assure their access to health, human service, rehabilitation, and housing programs. Funding should also increase the availability of vitally needed services such as active outreach, crisis stabilization in the normal environment, diminution of symptomatic behavior, remediation of functional skills, meaningful daytime activities, long-term supportive work opportunities, and case management.

5. *The same policy and implementation requirements* for classes of service, levels of care, and accountability that are required of public and private, state and local health systems and facilities should be applied to programs run directly by the federal government (i.e., the Veterans Administration and Public Health Service systems).

6. *Social and cultural factors.* There should be an equitable allocation of mental health resources in the community to citizens from all social, economic, and racial (ethnic) backgrounds and population densities. All services delivered must be adapted to meet the cultural values and perceptions or needs of various ethnic, minority, and subcultural groups.

7. *Utilization of families.* Wherever possible, patients' families should be involved in their treatment and care rather than depending on more expensive and less caring substitutes. While women in the home have traditionally assumed the caretaking responsibility, changing roles suggest that their presence can no longer be taken for granted; there must be adequate financial, social, and mental health supports available when families assume such responsibility.

RECOMMENDATIONS

Psychiatry's Role in the Care of Chronic Mentally Ill Patients

Since care of the chronic mentally ill patient is a major health concern to the public, it is incumbent on psychiatrists and other physicians to take an active role in attending to the needs of this population. Even though psychosocial problems may predominate, the medical and psychiatric needs of the chronic mentally ill require vigilant monitoring. In addition, psychiatrists have a responsibility in the development of comprehensive services for the chronic mentally ill and should be involved at all levels of program planning, public education, training, and research related to preventive care and rehabilitative services.

The American Psychiatric Association should take the lead in undertaking programs to elevate the prestige and value of work with chronic mentally ill patients. Portions of the scientific programs of annual meetings, regional meetings, and district branch scientific meetings should be devoted to this population. Research should be sponsored and groups working with this population should be encouraged. APA should also take steps to encourage psychiatrists and others to monitor the quality of care administered to the chronic mentally ill patient population by their peers.

The prestige and status of psychiatrists who work in programs with chronic mentally ill patients will be enhanced by affiliation with medical school departments of psychiatry; teaching and/or clinical assignments at medical schools by psychiatrists who work with the chronic mentally ill; clinical and supervisory assignments by faculty of academic departments to programs for chronic mentally ill patients; continuing medical education programs held at the site of programs for chronic patients by medical schools and APA district branches; academic appointments for psychiatrists working in programs for the chronic mentally ill patient; and a referral system involving private psychiatrists, which will ensure continuity of care.

Community Education

1. All involved consumer, professional, paraprofessional, and governmental bodies should mount a coordinated education and lobbying program, using professional communication expertise (lobbying, marketing, community education) to inform the public about the chronic mentally ill and how to meet their needs.

2. Community education must be oriented toward increasing the visibility and status of programs directed to chronic mental patients.

3. A major effort should be undertaken to develop a constituency for the chronic mentally ill patient population.

4. District branches should make an effort to include the subject of care and treatment of the chronic mentally ill in both their community and scientific programs.

Research

There must be a continuing emphasis on research in the area of chronic mental illness, including epidemiology, etiology, therapy, outcome, and effective service delivery. In addition, new efforts should be undertaken to clarify the conditions under which family care is helpful or harmful; to ascertain the rate and nature of problems faced by the (current) deinstitutionalized population as compared with the (formerly) institutionalized chronically ill population; to study the criteria for deinstitutionalization and for various types of group maintenance, including continued hospitalization; to define and refine the tasks, skills, and process of case management; and to reexamine the issues relating to confidentiality. Uniform data collection regarding the size, composition, and service needs of the chronic population at the local level is needed to help identify special problems and needs and to improve program planning and monitoring. Another fruitful area for research is the prevention of chronicity, especially in children and adolescents as well as in the aging.

Training

1. Training programs should be expanded or established for persons, including family members, in the skills appropriate to the needs of the chronic mentally ill.
2. Current professional training programs, including psychiatric residency programs, should be modified and reoriented toward an interdisciplinary focus to enhance the capacity of professionals to treat and care for the chronic mentally ill patient. Persons who have been working in chronic care settings should be retrained to be able to function within a community/rehabilitation model, nursing homes, and geriatric facilities, as well as in programs that help patients in strength assessment and the acquisition of the skills of everyday living.
3. Funding is required to implement the above retraining provisions and provide incentives for state governments to carry out this statutory responsibility where necessary. Consideration should be given to mechanisms whereby psychiatric residents could "pay back" the money spent on their training by serving in shortage areas (e.g., state hospitals).
4. Psychiatric residency training programs should be encouraged to include training for more chronic mentally ill patients than the 10 specified in the residency training guidelines, as well as to include training in administration and planning. Consideration should also be given to a new subspecialty—rehabilitation psychiatry.
5. A program for volunteer case aides should be established to promote local volunteer mobilization around the chronic mentally ill patient.
6. Training programs should be established for medical students and primary care physicians, especially those working in emergency settings, to focus on the special treatment needs of patients with chronic mental illness, since these patients have a higher incidence of medical illness and are often resistant to medical care due to their mental disability. Such programs should include experience with ambulatory chronically mentally ill patients, with particular emphasis on appropriate and inappropriate psychopharmacological medications, the concomitant social and vocational disabilities, and the full array of ambulatory treatment programs necessary for chronically ill patients.
7. The establishment of guidelines for training and career development of psychiatrists involved with program planning for and treatment of chronic mentally ill patients should be encouraged. A study of psychiatrists currently working in this area may offer data relevant to the development of successful educational experiences and career pathways.

Continuity and Provision of Services

1. Barriers should be removed to assure chronic mentally ill patients access to a full range of medical, psychiatric, rehabilitative, income maintenance, social, employment, and related opportunities and services appropriate to their needs in the least restrictive setting.
2. The system of care should be continuous between institutions and local programs, and there should be well developed systems for interservice program referral. It is necessary to establish and support case management to enable the chronically ill patient to use and benefit from community resources and programs. Such management should be based on a comprehensive treatment and management plan; the patient, and if possible the family, should be involved in the planning and delineation of responsibilities. Before extensive programs of case management are undertaken, however, there is a need to define the role, responsibility, and function of care, fixing of responsibility, and linking of hospitals with community services. Interagency linkage should be encouraged through inducements and sanctions written into legislation, regulations, and procedures. Adequate resources should be provided for case management functions, and funding should allow for an adequate period of time for training staff and establishing information systems, etc., to phase in such a system.

Financial Needs

The financial recommendations that follow include consideration of cost savings resulting from the shift of chronically ill patients from higher cost institutional programs to lower cost community alternatives. Attention to the ways in which financing mechanisms perpetuate higher cost care can prevent escalating and outrageous costs for programs serving chronic mentally ill patients. Some evidence exists that high quality integrated programs based on a least restrictive but full service model are no more costly than state hospital incarceration.

1. Programmatic funds should, as a long-term goal, flow from the federal to the state level and be earmarked for the chronic mentally ill patient where possible. This includes monies currently administered in the Departments of Health, Education, and Welfare, Housing and Urban Development, Labor, etc. Thus, a specified share of welfare, housing, rehabilitation, health, and mental health dollars would be directed to this population either on a capitation or index of need basis. These monies would be allocated to local communities or agencies only if programs were accountable in relation to the chronic mentally ill patients' needs for service.
2. On the federal level, structures should be created to provide oversight, both by Congress and the executive branch, of legislation and regulations affecting the needs of chronic mentally ill patients. A comparable structure should be established on the state and local levels.
3. The Department of Health, Education, and Welfare should perform a national survey of Medicare and Medicaid eligibility requirements, benefit services, and reimbursement schedules. This survey would elucidate current inequities and help establish national parity.
4. Chronic mentally ill patients are entitled to full participation in the health care system. Medicare, Medicaid, and

future national health insurance should not single out the chronic mentally ill as a class or discriminate against them in any way. This is especially important regarding private psychiatric care, which is often less costly than that provided by institutions.

5. Medicare, Medicaid, and future national health insurance benefits should include a full range of inpatient, day treatment, and outpatient services encompassing periodic medical and psychological evaluation and treatment, resocialization, and rehabilitation. In all future funding, there should be differentiation between health services (e.g., evaluation, diagnosis, medical, and psychiatric treatment) and social and supportive services (e.g., escort services, housing, etc.).

6. Any future national health insurance should also include cost effective but positive financial incentives to encourage professionals to care for the chronic mentally ill patient, so that the existing disincentives to providing long-term care are reversed.

7. Financing of psychiatric and human services should be modified to remove fiscal disincentives (e.g., Medicare restrictions on ambulatory care) and unnecessarily restrictive or debilitating settings or forms of care, such as inpatient hospitals or nursing homes.

8. All federally funded comprehensive community mental health centers should be required to provide comprehensive services to the chronically ill mental patient as one of the mandated essential services.

9. A federal technical assistance program, along the model of the agricultural extension program, should be developed to help localities develop appropriate programs for chronic mentally ill patients.

10. Funding mechanisms should encourage states and localities to move individuals out of the human services system into mainstream community life through rehabilitative programs.

11. Priority should be given to proposed systems ensuring that money follows chronic mentally ill patients, either through a voucher system that would enable patients to buy any or all necessary services or by some other mechanism.

12. There is agreement on the following points regarding recommendation 13 in the Preliminary Report of the President's Commission on Mental Health (advocating establishment of a class of intermediate care facilities for mental patients under Medicaid): there is a current *shortage of federal and state funding* for community living arrangements for the mentally disabled; there is a need for a *continuum* of types of living arrangements, offering varying degrees of supervision and support; funding policies should promote a planned, accountable *system* of living arrangements within each state and local planning area; there is a critical need for improved methods to *link* special living arrangements with nonresidential treatment, rehabilitation, and support services; and it is vital to recognize that appropriate living arrangements are *necessary* but not sufficient in meeting the needs of the mentally disabled.

Based on these areas of agreement, it is recommended that additional resources for community living arrangements for the mentally disabled be made available through earmarking federal and state housing and social service funds.

With respect to the advisability of specific federal funds for intermediate care facilities for the mentally ill, while we support the intent of the proposal, we believe that no such facilities should be established, because specific federal funding for a particular class of facilities will result in overdevelopment of one type of residential arrangement at the expense of other types, it will detract from the availability of adequate resources for essential nonresidential rehabilitation and support services, it will interfere with developing flexible local systems based on community needs, and it will be more expensive than a policy that would limit use of medical funds to more narrowly defined medical needs and would support housing arrangements from nonmedical resources.

13. Provisions of Supplemental Security Income legislation and procedures should be modified to replace the current disincentives against patients' returning to productive employment with positive incentives; e.g., allowances should be made for patients' rehabilitation potential.

Administrative Issues

As a long-term goal, the federal government should take responsibility for leadership and advocacy of care for the chronic mentally ill patient; establish policy and ensure consistency in all relevant agency policies; set basic programmatic guidelines and regulations; establish minimal care and accountability standards; issue guidelines setting forth broad parameters for the ulitization of funds; provide strong incentives and bonuses for care of the chronic mentally ill patient in the community; stimulate collaboration among agencies involved in policy planning and program implementation; develop technical assistance and disseminate information concerning the chronic mentally ill patient; develop criteria for determination of local government's ability to assume planning, management, and service operation responsibility and to establish programs for those localities without sufficient capacity to provide training, assistance, and funding to attain an acceptable level; and provide assurances that any jurisdictional level that has oversight/coordination responsibilities (and has reduced or eliminated its service operations) maintains the necessary staff expertise to carry out its responsibilities in the areas of planning, licensure, etc.

State governments should carry out the leadership, patient advocacy, and planning functions on a statewide basis for distribution of federal monies; supplement federal funds with state monies; and designate local authorities to have programmatic responsibility. They should also establish and provide assurances that coordination mechanisms are in place and operating to ensure chronically ill patients' access to appropriate support programs, develop appropriate standards for programs on a state level, establish regulatory/guideline appeals mechanisms, provide services for specific populations when it is not feasible for any other entity to assume this function, and monitor local service operations.

Local authorities should designate specific local entities to perform program activities; coordinate the planning and provision of services; hold local entities accountable for these services; establish entitlement for chronic mentally ill patients to relevant support systems; ensure nondiscrimination; ensure maximum consumer (public and nonprofit) participation; and provide local entities with formal authority over support-system resources such as welfare, rehabilitation, etc., applicable to this population.

Local entities should be the final common pathway for program funding directed toward providing the chronic mentally ill with a holistic integrated program based on the least restrictive, rehabilitative model with appropriate medical-psychiatric input. Local entities eligible for designation as the authority responsible for chronic mentally ill patients should include both public and nonprofit facilities.

The immediate goals should include the following:

1. Oversight mechanisms should be established at the fed-

eral level; examples are a select committee in Congress comparable to the Select Committee on Aging, and an executive branch equivalent, which would oversee federal legislation and regulations applying to chronic mentally ill patients.

2. Each state mental health authority should designate a single person/office to assume primary responsibility for acting in behalf of, planning, and supporting services for chronic mentally ill patients. Such person/office should develop knowledge about all potential federal and state programs that may provide funding and/or services for chronic mentally ill patients and transmit that knowledge to appropriate mental health service providers. Further, that person/office should review legislation, appropriations, and rules and regulations and should serve as an advocate for policies that will enhance services for chronic mentally ill patients.

3. Each state should produce a plan which guarantees that the needs of the chronically ill population will be provided for. Such plans should fix responsibility within each local planning area with a single community agency that assumes the role of convener, catalyst, coordinator, community organizer, and advocate for meeting the full range of needs of chronic mentally ill patients. The type of agency that can best assume this role may vary from community to community, depending on what is available. In all cases, it is essential that such responsibility be clearly assigned and recognized.

4. Clinical integration should be done by the local area health or mental health planning body independent of any care delivery system of its own that might represent a competitive interest. This also applies on the state level.

5. Accountability is a critical element to assure that the services promised are actually delivered. Evaluation of these services must be consistent and equally applicable to all service providers. Efforts should be made to limit the costs and bureaucracy of the evaluation process—possibly by utilizing the Health Systems Agency structure or an equivalent—and to encourage a positive attitude in enforcing accountability; i.e., evaluators should be oriented toward helping recipients satisfy not only regulatory requirements but also toward improving services, in addition to identifying service deficiencies and threatening penalties. Affirmative approaches to quality of life and social and vocational disabilities should be a primary objective.

6. Rather than building a whole new network of programs and services, the emphasis should be on the development of staff and facilities for the chronic mentally ill patient, making use of existing functions and resources, including the family whenever possible, and restructuring and reordering such programs in ways that better meet the needs of the chronic mentally ill patient. The development of new approaches and capacity should be encouraged at the local level, and technical assistance should be provided to enable this.

7. States should be discouraged from developing new state-operated facilities for chronic mentally ill patients and should phase down present facilities over time. While states must assure an adequate supply of facilities to meet the needs of chronic mentally ill patients, in order to encourage the local development of programs these facilities should not be state operated.

8. The federal government should eliminate any state or regional options in the utilization of essential federal funds, e.g., Section 8 of the Housing Law of 1975, and establish mechanisms whereby states and localities may appeal restrictive regulations.

Civil Rights

There should be federal legislation or regulations to accomplish the following:

1. *Prohibit discrimination against chronic mentally ill patients in vocational rehabilitation, employment, and education.* Specifically, Title VII of the Civil Rights Act of 1964 should be amended to prohibit "unjustified" discrimination in employment on the basis of handicap. In addition, there should be vigorous enforcement of Sections 503 and 504 of the Rehabilitation Act of 1973, federal legislation to encourage the hiring of the mentally handicapped (either through bonuses or tax incentives), and assurance that the severely and chronically mentally disabled are served by vocational rehabilitation agencies. Also, the concept of equal job opportunity should be applied to women in both institutional and community rehabilitative and vocational programs.

2. *Prohibit discrimination against chronic mentally ill patients in housing.* Specifically, Title VIII, Fair Housing, of the Civil Rights Act of 1968, should be amended to prohibit discrimination in housing on the basis of handicap. The Department of Housing and Urban Development should promulgate regulations to encourage states and localities to allocate additional Section 196 funds to develop more group care facilities, and to make additional Section 8 rental assistance funds available to mentally disabled persons living in group homes.

Federal legislation should be enacted encouraging the private market to provide housing to the mentally handicapped and conditioning receipt of federal revenue sharing or other funds to states having a plan for the development of community care and community residencies for the mentally disabled.

3. *Endorse the right to adequate treatment for both voluntary and involuntary patients in the hospital and the community, in the least restrictive setting consistent with individual treatment needs.* This includes the establishment of a mechanism whereby the patient may object to any aspect of his/her treatment plan, including transfer to another facility or to the community.

4. *Protect confidentiality, while allowing access to relevant information for legitimate treatment, planning, and research needs.* Centralized records should contain the minimum amount of information needed to meet the patient's future treatment needs, with access to records limited to a "need to know" basis, and patients should have the right to consent to the release of particular items of information from their records for time-limited periods, revocable by the patient. Stringent protection should govern access to treatment records, and stringent criminal penalties should be mandated for misuse of information included in records. Insurance claims (private and governmental) should be reviewed by a claims review system in which physicians would review patients' records without their names attached.

5. *Develop and fund an advocacy system independent of service providers to help ensure the implementation of patients' rights.* This system should either be part of the protection and advocacy system created by the Developmental Disabilities Act or should be modeled on that system.

6. *Prohibit zoning discrimination against the mentally ill by requiring that receipt of revenue sharing, housing, and other federal funds be predicated on the absence of exclusionary zoning laws or regulations in an area.*

7. *Enact a "Bill of Rights" for mentally disabled persons residing in the community.*

Position Statement on Active Treatment

This statement was approved by the Assembly at its meeting in October 1978 and by the Board of Trustees at its meeting in December 1978. The statement was originated by the Council on Mental Health Services[1] and revised by a special Assembly task force.[2]

PSYCHIATRIC TREATMENT is a planned effort on behalf of persons defined either by themselves or by their community as mentally ill or emotionally disturbed and in need of treatment. The person directing it must be qualified by specialized education and training to evaluate and understand the totality of the biological, psychological, and social factors that play a part in such an illness. Treatment is provided through medical procedures designed to benefit the ill person.

1. Treatment may begin prior to the establishment of a final diagnosis. The process of evaluation is an act of treatment.

2. The standards used by a community to judge behavior may not always be in agreement with the standards leading to a diagnosis used by a psychiatrist to judge behavior. For example, some people judged by community standards to be "bad" rather than ill may suffer from a diagnosable mental illness. On the other hand, some persons whose behavior is identified as aberrant by a given community may be perceived by the psychiatrist as following an alternative lifestyle and not as suffering from an illness.

3. As in physical illness, an individual's subjective distress may in itself be sufficient justification for treatment.

4. Psychiatric disorders result from the complex interaction of physical, psychological, and social factors and treatment may be directed toward any or all three of these areas.

5. Treatment may include measures to maintain current functioning and prevent further deterioration as well as measures designed to improve or eliminate dysfunction.

6. A variety of professional disciplines may be involved in a treatment program. The extent and kind of participation of any practitioner in a specific treatment program should be determined by the person primarily responsible for providing treatment. The professional qualifications and ethics of the various disciplines are defined by each professional group within society's sanctions. No practitioner should be required to participate in a manner contrary to the ethic of his or her discipline.

7. A formal or informal treatment plan is an integral part of treatment. The plan should include the goals of treatment and problems that may be anticipated and should be revised when appropriate and indicated. Psychiatric treatment should be based on principles that can be explained and communicated during review by one's peers.

8. Providing a human environment for the care of persons in need is not equivalent to providing treatment. However, when the environment is carefully organized to respond in a therapeutic manner to patients' needs and behavior and is staffed and supervised by qualified members of appropriate professional disciplines, it is a form of treatment. Treatment of that kind is usually referred to as a therapeutic environment or milieu therapy.

9. Psychiatric treatment is the sum of the activities of a psychiatrically qualified physician in meeting the therapeutic needs of a patient, a family, or a (community) group. This may include the supervision of others who are providing treatment and for whose activities the psychiatrist accepts professional and legal responsibility.

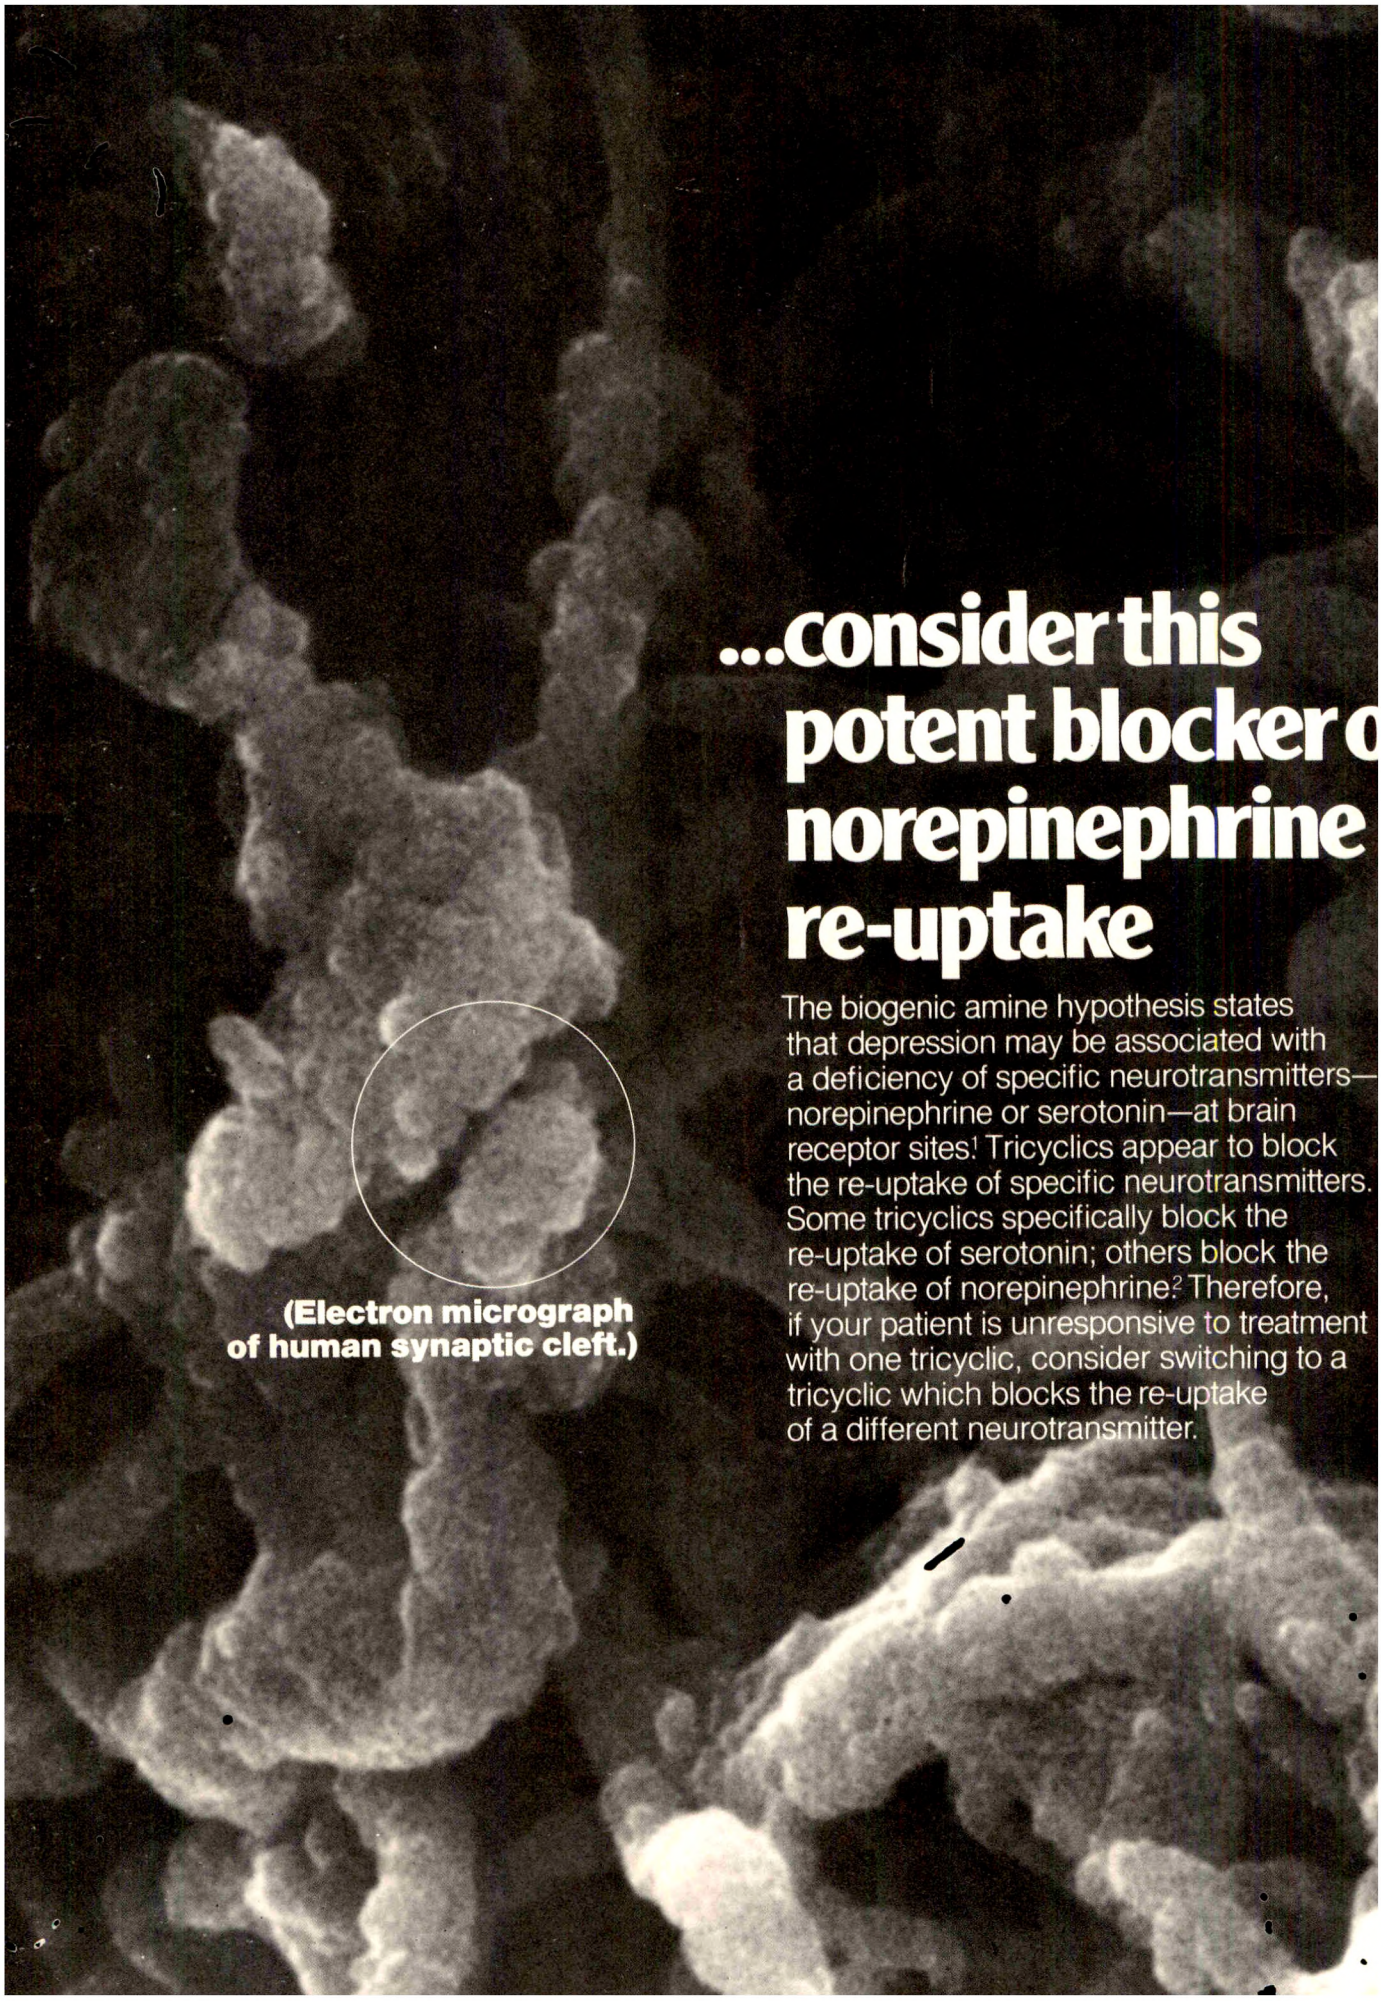
[1]The Council on Mental Health Services included J.M. Stubblebine, M.D., chairperson, Mildred Mitchell-Bateman, M.D., Israel Zwerling, M.D., Hayden H. Donahue, M.D., Alan Elkins, M.D., Aubrey Dent, M.D. (observer-consultant), Jack Kremens, M.D. (Assembly liaison), Robert W. Gibson, M.D. (Board liaison), Donald G. Langsley, M.D. (Board liaison), Richard T. Rada, M.D. (consultant), and Donald Hammersley, M.D. (staff assigned).

[2]This task force included Warren S. Williams, M.D., chairperson, Roy M. Coleman, M.D., Lino Covi, M.D., and Roger Peele, M.D.

Am J Psychiatry 136:5, May 1979

Position Statement on Marijuana Laws

This statement was approved by the Assembly at its October 1978 meeting, by the Reference Committee at its November 1978 meeting, and by the Board of Trustees at its December 1978 meeting upon recommendation of the Council on Research and Development. It was prepared by the Council on Research and Development.[1]



MARIJUANA IS now the third most popular recreational drug in the United States, after tobacco and alcohol. There appears to be no convincing evidence of serious lasting physical or psychological damage caused by moderate or intermittent use in healthy adults. Nonetheless, there have been more than 400,000 marijuana arrests annually for the last four years, at an estimated administrative cost of $600 million a year and an immeasurable cost in damage to the lives of many young people and their families. For the vast majority of users the main danger is being convicted of a crime. Thus, the present situation promotes disrespect for the law and has a destructive effect on efforts to present the dangers of drugs honestly to the public.

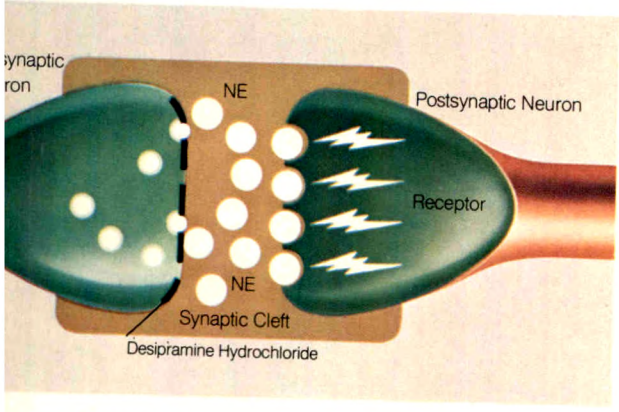
In 1972 the National Marijuana Commission concluded that "neither the marijuana user nor the drug itself can be said to constitute a danger to the public safety." It recommended the elimination of criminal penalties against the user. This policy, known as decriminalization, has been endorsed by a lengthening list of organizations, including the American Bar Association, the American Public Health Association, the National Education Association, the National Council of Churches, the Mental Health Association, and the governing board of the American Medical Association. President Carter supports decriminalization at the federal level, and 10 states have enacted decriminalization laws without producing any harmful effects or even any increase in marijuana use. The 1969 position statement of the American Psychiatric Association calls for "the cessation of disproportionate penalties for marijuana possession and use." Any criminal penalty for the possession of small amounts of marijuana for personal use can now be properly described as disproportionate, and decriminalization would fulfill the intent of the phrase used in 1969 as it has come to be interpreted by a large section of informed opinion. The Board of Trustees of the American Psychiatric Association therefore goes on record as supporting a policy of decriminalization.

This position statement is in no way to be construed as an endorsement of the social and recreational, particularly habitual, use of marijuana. Much research needs to be done concerning the nature of the action and effects, particularly long-term ones, of the drug, and until this knowledge is available, use of the drug must be considered potentially hazardous.

[1]The Council on Research and Development included Lester Grinspoon, M.D., chairperson, Charles Gaitz, M.D., Frank A. DeLeon-Jones, M.D., Edward Joel Sachar, M.D., John M. Davis, M.D., Joyce Lowinson, M.D. (observer-consultant), Leigh Roberts, M.D. (Assembly liaison), and Henry H. Work, M.D. (staff assigned).

When your patient is clinically depressed...
"...everything I saw was negative."

...consider this potent blocker o norepinephrine re-uptake



The biogenic amine hypothesis states that depression may be associated with a deficiency of specific neurotransmitters—norepinephrine or serotonin—at brain receptor sites.[1] Tricyclics appear to block the re-uptake of specific neurotransmitters. Some tricyclics specifically block the re-uptake of serotonin; others block the re-uptake of norepinephrine.[2] Therefore, if your patient is unresponsive to treatment with one tricyclic, consider switching to a tricyclic which blocks the re-uptake of a different neurotransmitter.

(Electron micrograph of human synaptic cleft.)

Norpramin®
desipramine hydrochloride ablets NF)
5, 50, 75, 100, 150 mg.

tent blocker norepinephrine re-uptake

cording to current theory[1,3] some cyclic antidepressants may fail in certain es of depression because they are not ficiently potent blockers of norepi-hrine re-uptake. Laboratory studies ve shown that desipramine is the most ent inhibitor of norepinephrine uptake.[4] Norpramin may work in some ients when other tricyclic antidepres-nts do not.

onsider it now, nsider it next.

Less anticholinergic activity

(See Warnings section.)

Studies in animals[5] and in normal human subjects[6,7] have shown that desipramine has significantly less anticholinergic activity than amitriptyline or doxepin. The single bond side chain is associated with lower anticholinergic activity than these other leading antidepressants. This may mean:

- less dry mouth
- less blurred vision
- less urinary retention

Helps patients remain calm but active

Norpramin does not usually inhibit normal activity although patients should be cautioned as to driving or operating machinery if drowsiness occurs.

In addition...

Begins to improve sleep patterns within one week in some patients[8]

- Norpramin helps relieve the sleep disturbances that often accompany depression.
- As the depression is relieved, the difficulty in falling asleep, restlessness, and early morning awakening diminish.

Merrell

Now 300 mg. dosage range broadens clinical flexibility

A maximum dosage of 300 mg. a day, as a single or divided dose, may now be prescribed Norpramin. Since inadequate dosage is thought to be one of the major causes of treatment failure, the new therapeutic range should prove clinically helpful. Plasma desipramine measurement would constitute the optimal guide to dosage monitoring.

Norpramin®
(desipramine hydrochloride tablets NF)

AVAILABLE ONLY ON PRESCRIPTION

Brief Summary

MECHANISM OF ACTION: Available evidence suggests that many depressions have a biochemical basis in the form of a relative deficiency of neurotransmitters such as norepinephrine and serotonin. Norepinephrine deficiency may be associated with relatively low urinary 3-methoxy-4-hydroxyphenyl glycol (MHPG) levels, while serotonin deficiencies may be associated with low spinal fluid levels of 5-hydroxyindolacetic acid.

While the precise mechanism of action of the tricyclic antidepressants is unknown, a leading theory suggests that they restore normal levels of neurotransmitters by blocking the re-uptake of these substances from the synapse in the central nervous system.

Evidence indicates that the secondary amine tricyclic antidepressants, including Norpramin, may have greater activity in blocking the re-uptake of norepinephrine. Tertiary amine tricyclic antidepressants, such as amitriptyline, may have greater effect on serotonin re-uptake.

Norpramin (desipramine hydrochloride) is not a monoamine oxidase (MAO) inhibitor and does not act primarily as a central nervous system stimulant. It has been found in some studies to have a more rapid onset of action than imipramine. Earliest therapeutic effects may occasionally be seen in 2 to 5 days, but full treatment benefit usually requires 2 to 3 weeks to obtain.

INDICATIONS: Norpramin (desipramine hydrochloride) is indicated for relief of symptoms in various depressive syndromes, especially endogenous depression.

CONTRAINDICATIONS: Desipramine hydrochloride should not be given in conjunction with, or within 2 weeks of, treatment with an MAO inhibitor drug; hyperpyretic crises, severe convulsions, and death have occurred in patients taking MAO inhibitors and tricyclic antidepressants. When Norpramin (desipramine hydrochloride) is substituted for an MAO inhibitor, at least 2 weeks should elapse between treatments. Norpramin should then be started cautiously and should be increased gradually.

The drug is contraindicated in the acute recovery period following myocardial infarction. It should not be used in those who have shown prior hypersensitivity to the drug. Cross sensitivity between this and other dibenzazepines is a possibility.

WARNINGS: 1. Extreme caution should be used when this drug is given in the following situations: a. In patients with cardiovascular disease, because of the possibility of conduction defects, arrhythmias, tachycardias, strokes, and acute myocardial infarction. b. In patients with a history of urinary retention or glaucoma, because of the anticholinergic properties of the drug. c. In patients with thyroid disease or those taking thyroid medication, because of the possibility of cardiovascular toxicity, including arrhythmias. d. In patients with a history of seizure disorder, because this drug has been shown to lower the seizure threshold. **2.** This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. **3.** USE IN PREGNANCY: Safe use of desipramine hydrochloride during pregnancy and lactation has not been established; therefore, if it is to be given to pregnant patients, nursing mothers, or women of childbearing potential, the possible benefits must be weighed against the possible hazards to mother and child. Animal reproductive studies have been inconclusive. **4.** USE IN CHILDREN: Norpramin (desipramine hydrochloride) is not recommended for use in children since safety and effectiveness in the pediatric age group have not been established. **5.** The patient should be cautioned that this drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. **6.** In patients who may use alcohol excessively, it should be borne in mind that the potentiation may increase the danger inherent in any suicide attempt or overdosage.

PRECAUTIONS: 1. It is important that this drug be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with this class of drug. Ordinary prudence requires that children not have access to this drug or to potent drugs of any kind; if possible this drug should be dispensed in containers with child-resistant safety closures. Storage of this drug in the home must be supervised responsibly. **2.** If serious adverse effects occur, dosage should be reduced or treatment should be altered. **3.** Norpramin (desipramine hydrochloride) therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates. **4.** The drug may cause exacerbation of psychosis in schizophrenic patients. **5.** Close supervision and careful adjustment of dosage are required when this drug is given concomitantly with anticholinergic or sympathomimetic drugs. **6.** Patients should be warned that while taking this drug their response to alcoholic beverages may be exaggerated. **7.** Clinical experience in the concurrent administration of ECT and antidepressant drugs is limited. Thus, if such treatment is essential, the possibility of increased risk relative to benefits should be considered. **8.** The sedative effects of Norpramin and benzodiazepines (*e.g.*, chlordiazepoxide or diazepam) are additive. Both the sedative and anticholinergic effects of the major tranquilizers are additive to those of Norpramin. **9.** This drug should be discontinued as soon as possible prior to elective surgery because of the possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients taking desipramine hydrochloride. **10.** Both elevation and lowering of blood sugar levels have been reported. **11.** Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathologic neutrophil depression.

ADVERSE REACTIONS: Note: Included in the following listing are a few adverse reactions that have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when Norpramin (desipramine hydrochloride) is given.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions, anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurologic: numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus.

Anticholinergic: dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis, increased intraocular pressure; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs.

Hematologic: bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue.

Endocrine: gynecomastia in the male, breast enlarg ment and galactorrhea in the female; increased decreased libido, impotence, testicular swelling; elev tion or depression of blood sugar levels.

Other: jaundice (simulating obstructive), altered liv function; weight gain or loss; perspiration, flushi urinary frequency, nocturia; parotid swelling; drow ness, dizziness, weakness and fatigue, headache; a pecia.

Withdrawal Symptoms: Though not indicative of add tion, abrupt cessation of treatment after prolon therapy may produce nausea, headache, and malai

DOSAGE AND ADMINISTRATION: Not recommended for u in children. Lower dosages are recommended for elde patients and adolescents. Lower dosages are a recommended for outpatients compared to hospitali patients, who are closely supervised. Dosage should initiated at a low level and increased according clinical response and any evidence of intolerar Following remission, maintenance medication may required for a period of time and should be at the low dose that will maintain remission.

Usual Adult Dose: The usual adult dose is 100 to 200 per day. In more severely ill patients, dosage may further increased gradually to 300 mg./day if necess Dosages above 300 mg./day are not recommended.

Dosage should be initiated at a lower level increased according to tolerance and clinical respo

Treatment of patients requiring as much as 300 should generally be initiated in hospitals, where reg visits by the physician, skilled nursing care, and quent electrocardiograms (ECG's) are available.

The best available evidence of impending toxi from very high doses of Norpramin is prolongation o QRS or QT intervals on the ECG. Prolongation of th interval is also significant, but less closely correl with plasma levels. Clinical symptoms of intolera especially drowsiness, dizziness, and postural hypo sion, should also alert the physician to the nee reduction in dosage. Plasma desipramine measure would constitute the optimal guide to dosage mon ing.

Initial therapy may be administered in divided d or a single daily dose.

Maintenance therapy may be given on a once- schedule for patient convenience and compliance.

Adolescent and Geriatric Dose: The usual adolescen geriatric dose is 25 to 100 mg. daily.

Dosage should be initiated at a lower level increased according to tolerance and clinical resp to a usual maximum of 100 mg. daily. In more sever patients, dosage may be further increased to 150 day. Doses above 150 mg./day are not recommend these age groups.

Initial therapy may be administered in divided or a single daily dose.

Maintenance therapy may be given on a once- schedule for patient convenience and compliance.

OVERDOSAGE: See prescribing information for a di sion of symptoms and treatment of overdose.

Stress control your patients can see and hear: GSR/Temp 2.

Extensive clinical papers attest to the value of biofeedback therapy as a natural alternative or adjunct in the treatment of anxiety/tension states. The advantages of the GSR/TEMP 2 system have been demonstrated in thousands of hospitals and educational facilities worldwide—enabling patients to learn a degree of voluntary control over tension related autonomic responses.

Both decreases in skin resistance as well as constriction of peripheral vasculature resulting in minor temperature changes are well recognized indicators of increases in both physical and mental stress. Only now have advances in electronic technology allowed the development of the first and only portable, inexpensive unit which is easy for the patient to adapt to and monitors these dual functions—the GSR/TEMP 2 *monitors both temperature and skin resistance!*

Temperature changes (of .05°C) are monitored through a thermistor probe which is placed on a finger. Skin Resistance is monitored through built in sensors or through remote electrodes. Feedback is either auditory from an internal speaker or earphone or visual from a meter.

The GSR/TEMP 2 is the *only* biofeedback system available in this lightweight form which incorporates both temperature and skin resistance as indicators of sympathetic nervous system activity.

The new GSR/TEMP 2 dual system is a complete unit including monitor, temperature sensor, earphone, read-out meter, remote monitoring electrodes, instruction cassette & record and manual. *It is the first time a compact and functional unit has been developed which is equally suitable for clinical or home use.*

15 Day Free Examination

Thought Technology Ltd., 2193 Clifton Ave., Montreal, Quebec, Canada H4A 2N5

Please send me _____ GSR 2 Kits at **$39.95**. each (plus $2.95 shipping and handling)

I prefer: ☐ Cassette, ☐ LP record.

I would also like the following optional equipment:

☐ Thermistor, $15.95, ☐ Meter, $12.95, ☐ Electrodes, $9.95, ☐ Carrying case, $12.95

Please send me instead _____ sets of the complete GSR/TEMP 2 Biofeedback System at $79.95 each (plus $3.95 shipping and handling).

I may return any of the equipment within 15 days for a complete refund. Full one year guarantee.

Residents of Quebec add 8% sales tax. Postage and handling outside North America: GSR2—$5.00; GSR/TEMP 2—$10.00. All U.S. orders sent from our N.Y. warehouse via U.P.S.

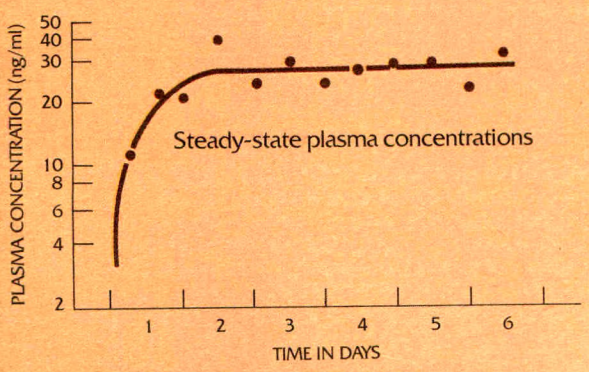
How to tell ATIVAN from other benzodiazepines.

Ativan is an effective, well-tolerated antianxiety agent. So are other benzodiazepines. But here are three ways Ativan stands out pharmacokinetically.*

1. Uncomplicated metabolic profile.

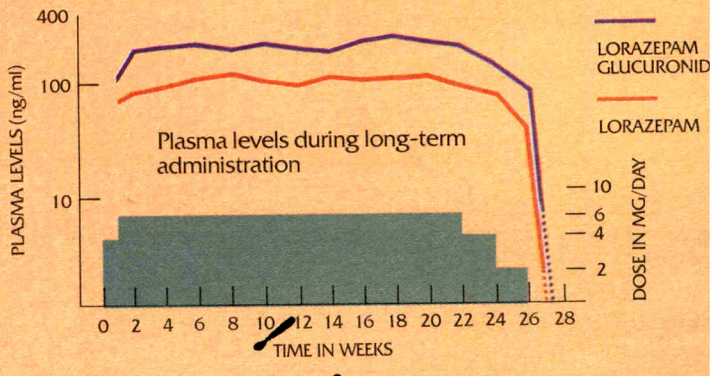
In contrast to most other benzodiazepines, the metabolic pathway of Ativan is straightforward. Ativan is active as given. Just one step from an active compound to an inactive one.

2. Steady-state levels achieved rapidly.



Most benzodiazepines take at least 7 to 10 days to reach steady-state serum levels. With Ativan, that equilibrium is reached in 2 to 3 days. A factor that can be important when you modify dosage schedules to meet individual needs.

3. No accumulation of multiple metabolites.

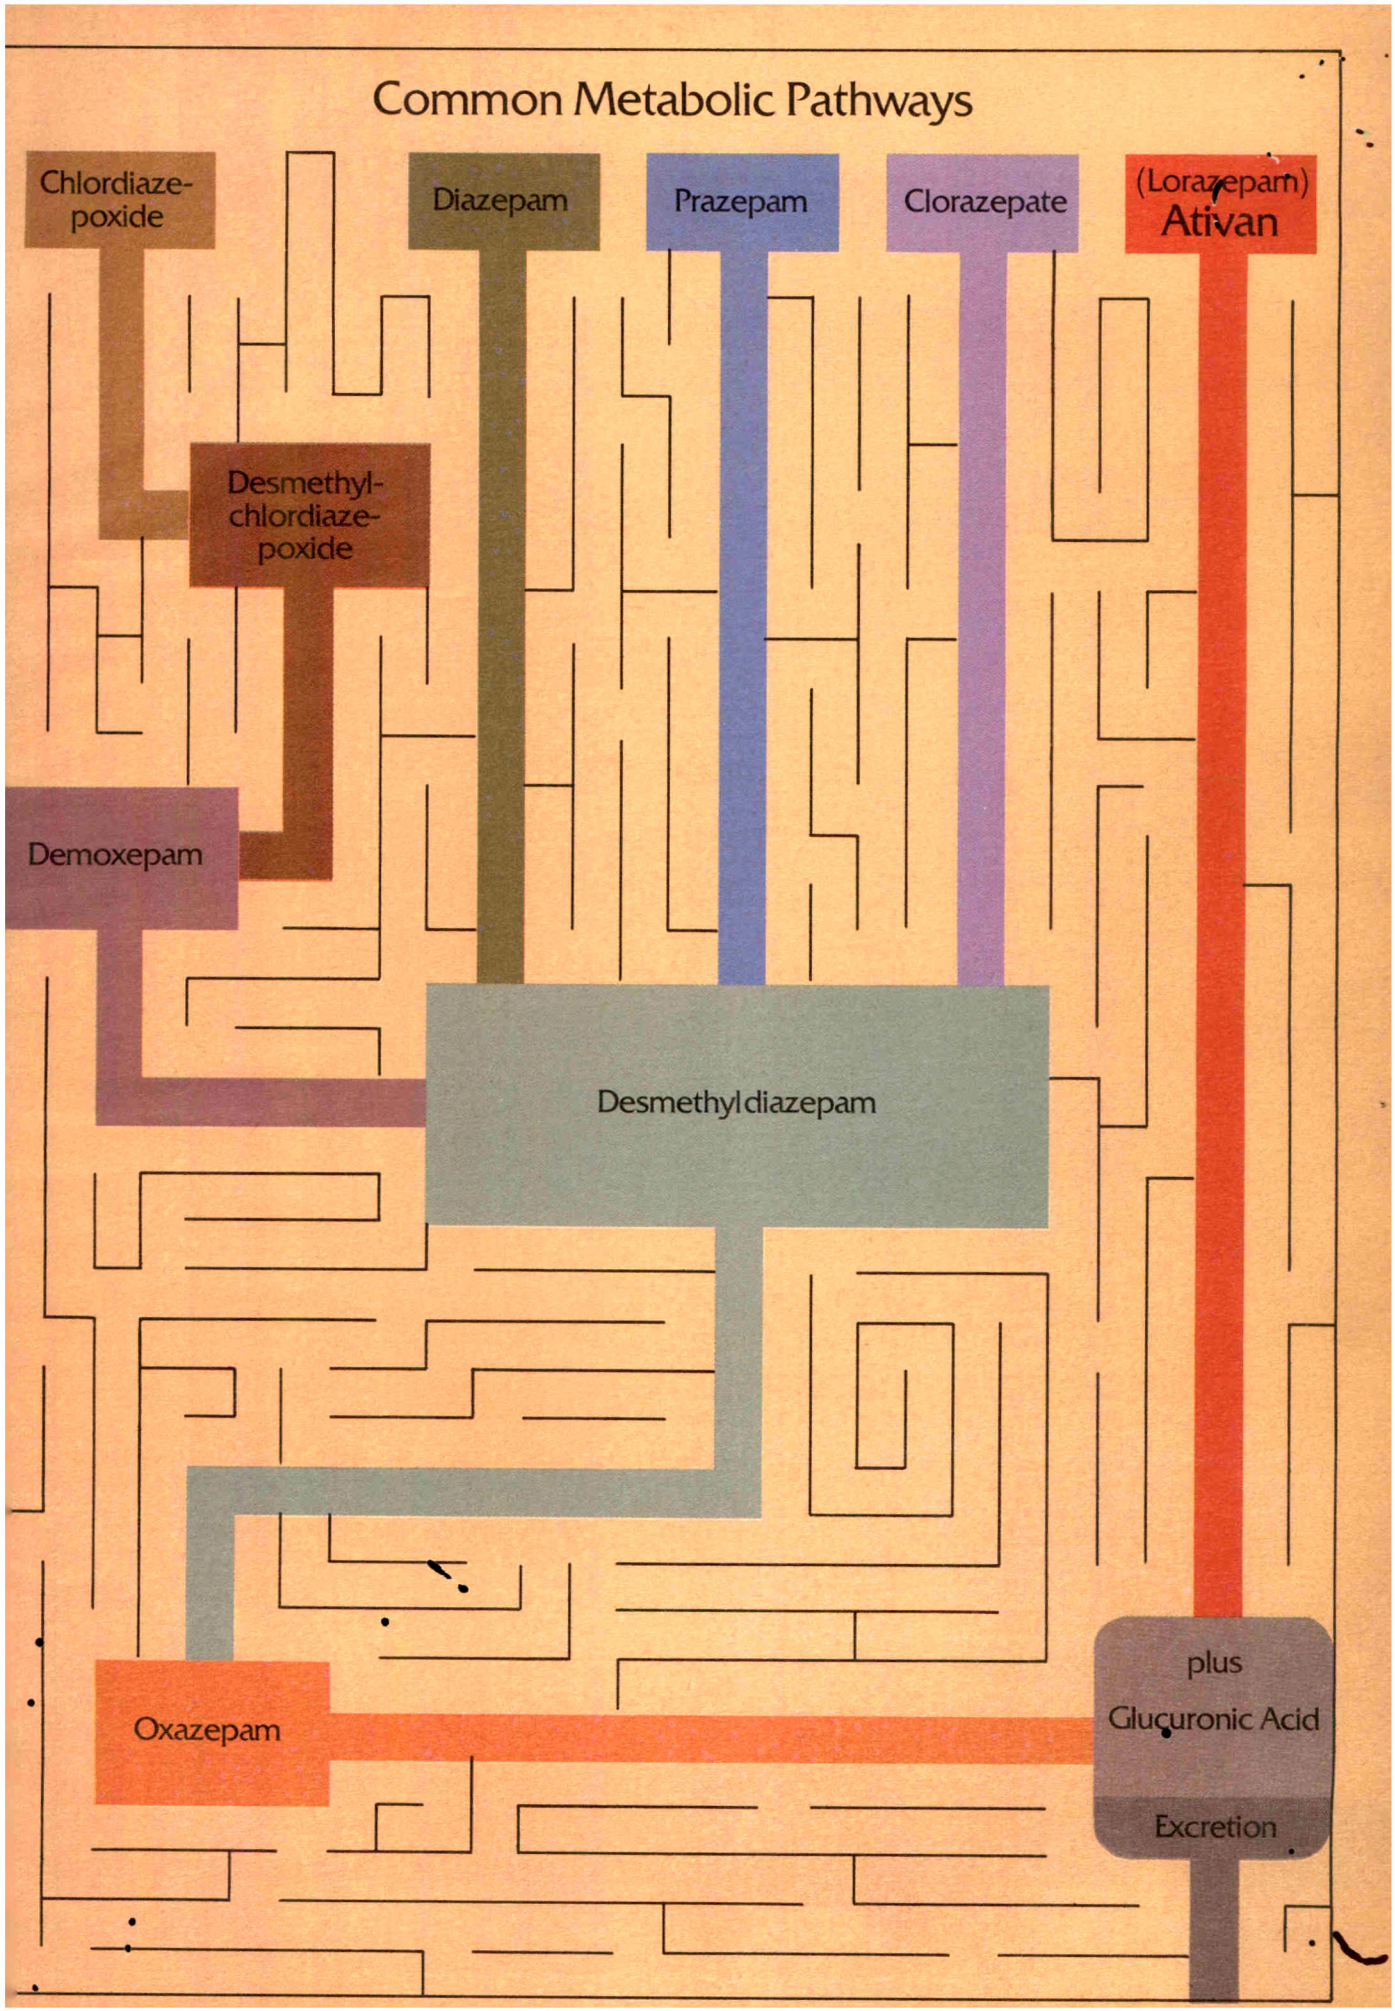


Because Ativan has no active metabolites to be eliminated at varying rates, steady-state levels are achieved predictably and smoothly. Six-month studies show no evidence of drug-accumulation above steady-state levels even at maximum daily dosages.

*The pharmacokinetic profile of a drug cannot, at present, be directly related to its therapeutic effectiveness.

Please refer to page after next for a summary of prescribing information.

Concentrations of lorazepam on repeated-dose regimen (single 1-mg. tablets given at 9 a.m., 3 p.m. and 9 p.m. daily for 6 days). A steady state is achieved after the second day, and is maintained thereafter.



Lorazepam and lorazepam glucuronide plasma levels in ng/ml during chronic oral administration of the drug over a period of six months. Each point represents the mean of 8 subjects. The daily maintenance dose in milligrams per subject is given at weekly intervals.

prescribing information

Contraindications: Ativan is contraindicated in patients with known sensitivity to the benzodiazepines or with acute narrow-angle glaucoma.

Warnings: Ativan is not recommended for use in patients with a primary depressive disorder or psychosis. As with all patients on CNS-acting drugs, patients receiving lorazepam should be warned not to operate dangerous machinery or motor vehicles and that their tolerance for alcohol and other CNS depressants will be diminished.

Physical and Psychological Dependence: Withdrawal symptoms similar in character to those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepine drugs. These symptoms include convulsions, tremor, abdominal and muscle cramps, vomiting and sweating. Addiction-prone individuals, such as drug addicts and alcoholics, should be under careful surveillance when receiving benzodiazepines because of the predisposition of such patients to habituation and dependence.

Precautions: In patients with depression accompanying anxiety, a possibility for suicide should be borne in mind.

For elderly or debilitated patients, the initial daily dosage should not exceed 2 mg in order to avoid oversedation.

Ativan dosage should be terminated gradually since abrupt withdrawal of any antianxiety agent may result in symptoms similar to those for which patients are being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

The usual precautions for treating patients with impaired renal or hepatic function should be observed.

In patients where gastrointestinal or cardiovascular disorders coexist with anxiety, it should be noted that lorazepam has not been shown to be of significant benefit in treating the gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than one year at 6 mg/kg/day. The no-effect dose was 1.25 mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10 mg per day). The effect was reversible only when the treatment was withdrawn within two months of first observation of the phenomenon. The clinical significance of this is unknown. However, use of lorazepam for prolonged periods and in geriatric patients requires caution, and there should be frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness of Ativan in children of less than 12 years have not been established.

Essential Laboratory Tests: Some patients on Ativan have developed leukopenia and some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended for patients on long-term therapy.

Clinically Significant Drug Interactions: The benzodiazepines including Ativan produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

Carcinogenesis and Mutagenesis: No evidence of carcinogenic potential emerged in rats during an 18-month study with Ativan. No studies regarding mutagenesis have been performed.

Pregnancy: Reproductive studies in animals were performed in mice, rats, and two strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all of these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At doses of 40 mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses.

The clinical significance of the above findings is not known. However, an increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during the first trimester of pregnancy has been suggested in several studies. Because the use of these drugs is rarely a matter of urgency, the use of lorazepam during this period should almost always be avoided. The possibility that a woman of child-bearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant, they should communicate with their physician about the desirability of discontinuing the drug.

In humans, blood levels obtained from umbilical cord blood indicate placental transfer of lorazepam and lorazepam glucuronide.

Nursing Mothers: It is not known whether oral lorazepam is excreted in human milk like the other benzodiazepine tranquilizers. As a general rule, nursing should not be undertaken while a patient is on a drug since many drugs are excreted in human milk.

Adverse Reactions: Adverse reactions, if they occur, are usually observed at the beginning of therapy and generally disappear on continued medication or upon decreasing the dose. In a sample of about 3,500 anxious patients, the most frequent adverse reaction to Ativan is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent adverse reactions are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, together with various gastrointestinal symptoms and autonomic manifestations. The incidence of sedation and unsteadiness increased with age.

Small decreases in blood pressure have been noted but are not clinically significant, probably being related to the relief of anxiety produced by Ativan.

Overdosage: In the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

Manifestations of Ativan overdosage include somnolence, confusion and coma. Induced vomiting and/or gastric lavage should be undertaken followed by general supportive care, monitoring of vital signs and close observation of the patient. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection, U.S.P. Caffeine and Sodium Benzoate Injection, U.S.P. may be used to counteract CNS depressant effects. The usefulness of dialysis has not been determined.

Dosage and Administration: Ativan is administered orally. For optimal results, dose, frequency of administration and duration of therapy should be individualized according to patient response. To facilitate this, scored 1.0 and 2.0 mg tablets are available.

The usual range is 2 to 6 mg/day given in divided doses, the largest dose being taken before bedtime, but the daily dosage may vary from 1 to 10 mg/day. For anxiety, most patients require an initial dose of 2 to 3 mg/day given b.i.d. or t.i.d.

For insomnia due to anxiety or transient situational stress, a single daily dose of 2 to 4 mg may be given, usually at bedtime.

For elderly or debilitated patients, an initial dosage of 1 to 2 mg/day in divided doses is recommended, to be adjusted as needed and tolerated.

The dosage of Ativan should be increased gradually when needed to help avoid adverse effects. When higher dosage is indicated, the evening dose should be increased before the daytime doses.

How Supplied: Ativan (lorazepam) is available in scored 1.0 and 2.0 mg tablets in bottles of 100.

MEDICAL DIRECTOR OF ALCOHOLISM THERAPY PROGRAM

The Department of Substance Abuse of Henry Ford Hospital, a comprehensive health care delivery system that integrates clinical and basic scientific research and medical education with innovative health services in Detroit and its surrounding communities, is seeking a Medical Director for its Alcoholism Therapy Program. Duties will include supervising the medical care of a 14-bed inpatient unit at the main hospital and assisting in the development for a plan for a new suburban 50-bed residential and outpatient facility and providing inservice education and research. We offer a competitive salary and liberal fringe benefits. Interested parties should send their curriculum vitae, in strict confidence, to:

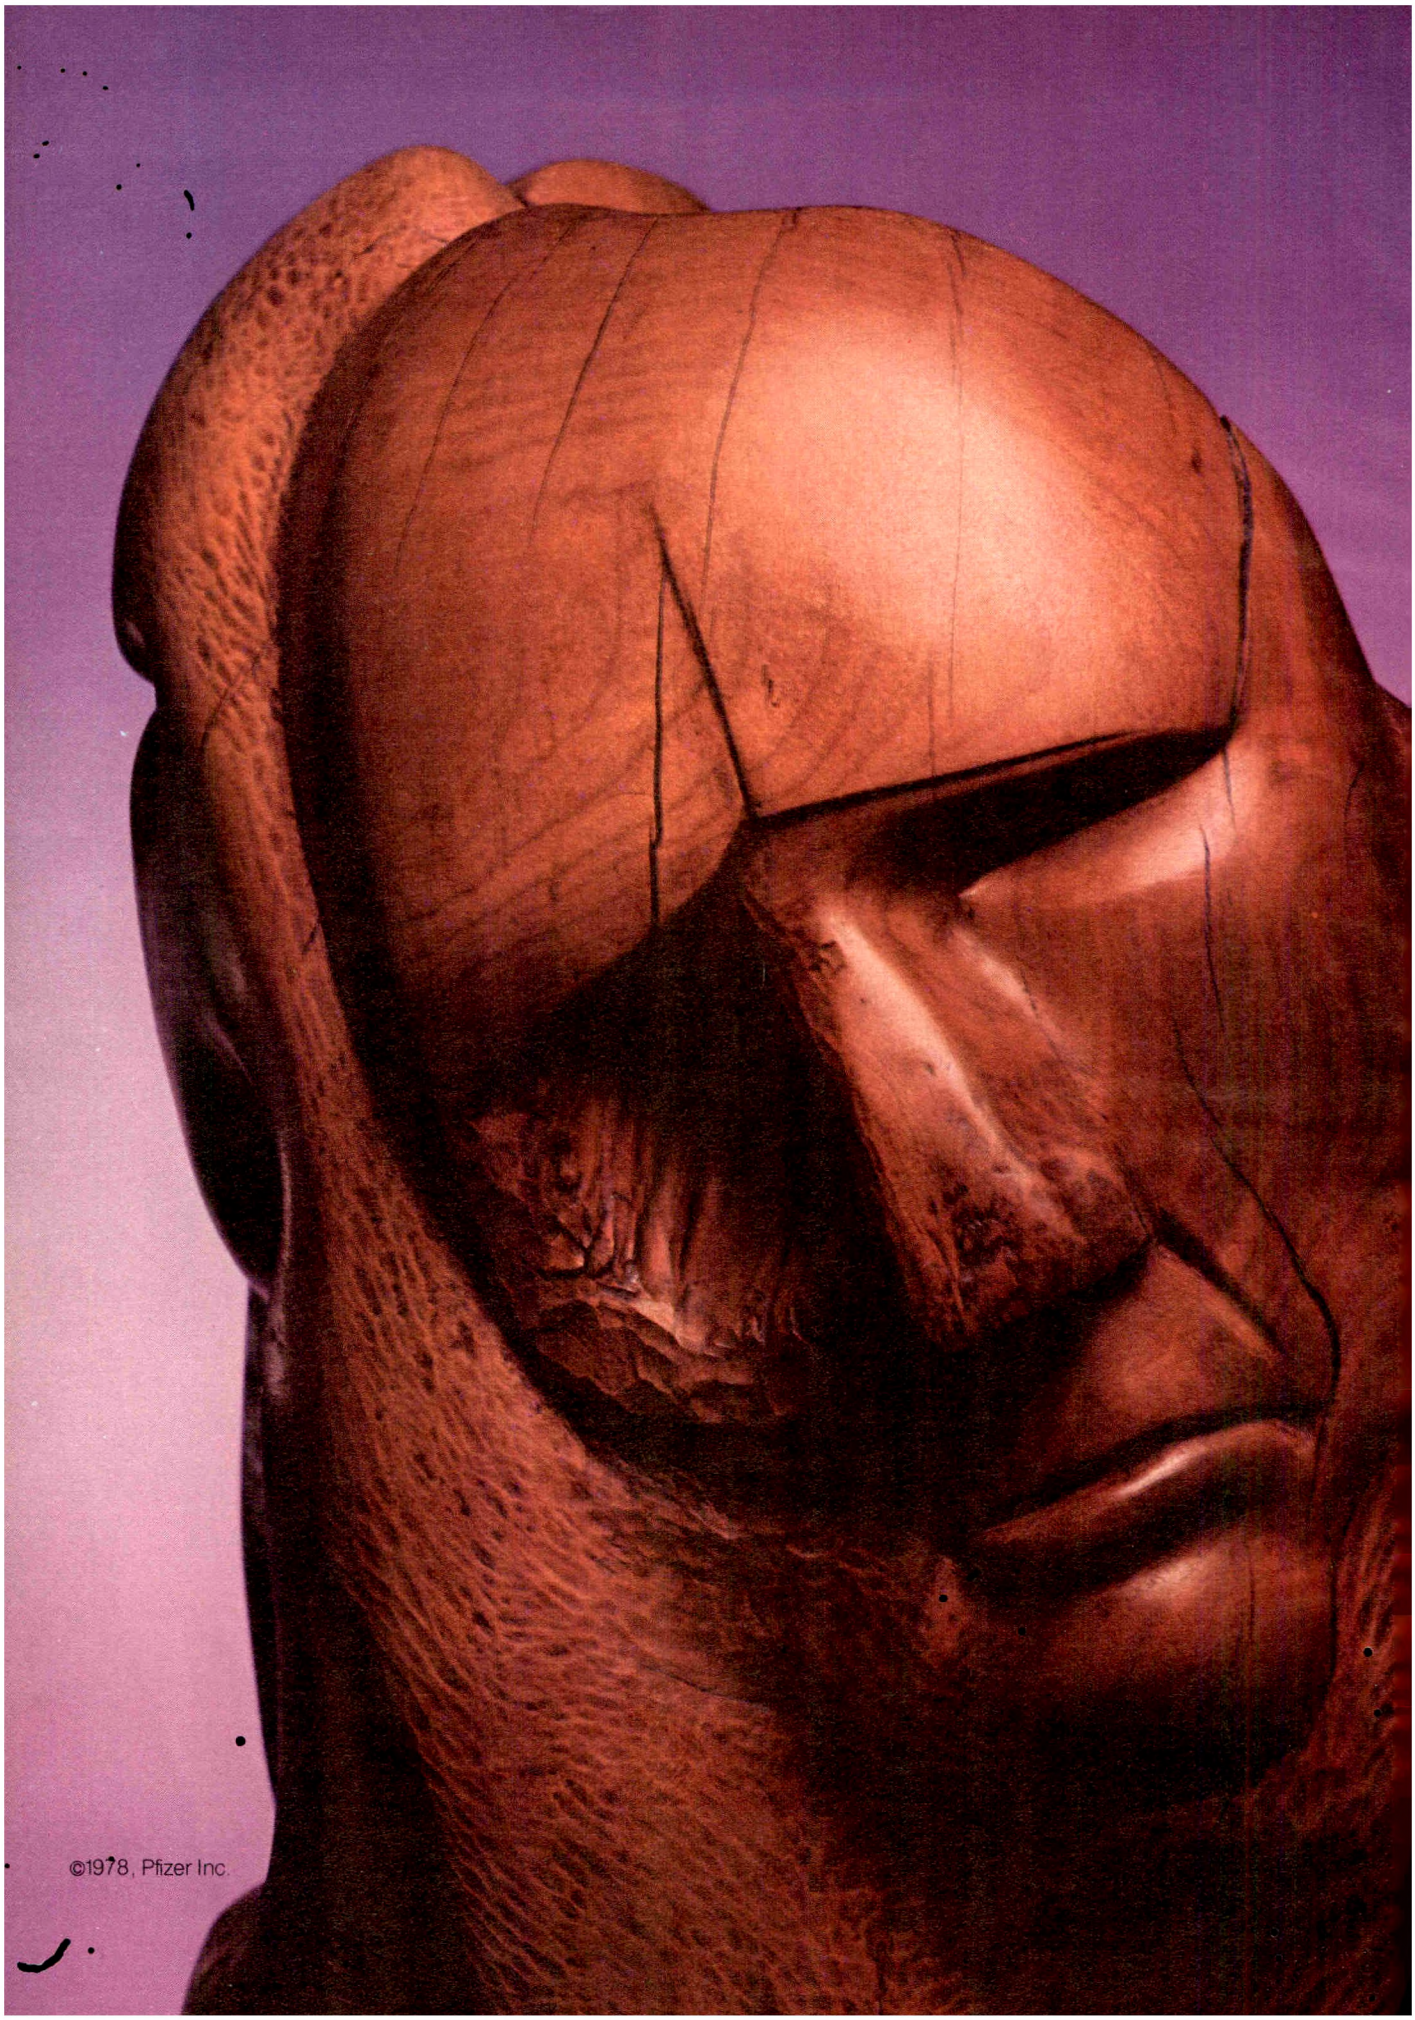
Bernard Schuman, M.D.
Chairperson, Search Committee
Department of Substance Abuse
2799 West Grand Blvd. — Office A573W
Detroit, Michigan 48202

Director of Adolescent Psychiatry

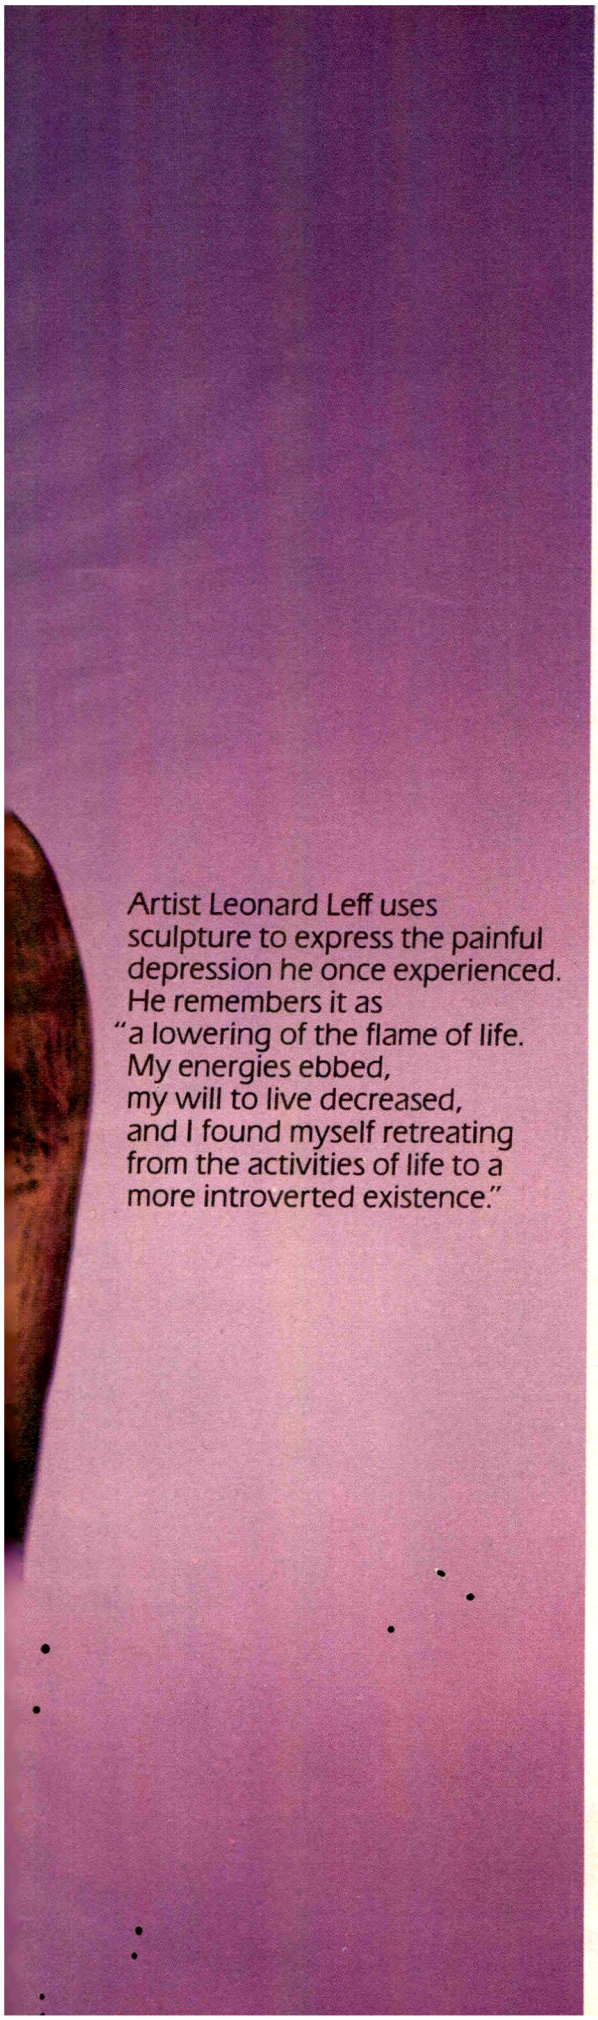
343 bed suburban Detroit area hospital has a full-time staff vacancy for the newly created position of Director of the Adolescent Psychiatric Program. A new 40-bed inpatient unit is under construction to accommodate this program scheduled for opening in October, 1979.

The Hospital presently has an inpatient unit of 38 beds for adults and adolescents, a partial hospitalization (day care) program, an outpatient psychiatric clinic and a Psychology Department.

An excellent total compensation program has been designed for this position including negotiable salary and comprehensive benefit and retirement programs.



Interested board certified Psychiatrists (Adolescent and Child Psychiatry) wishing to apply for the position should submit their curriculum vitae in confidence or call collect if they so desire. Contact BRUCE L. NELSON, VICE PRESIDENT FOR MEDICAL SERVICES, WYANDOTTE GENERAL HOSPITAL, 2333 BIDDLE AVENUE, WYANDOTTE, MI, 48192. PHONE (313) 284-2400, ext. 2504.



NATIONAL PSYCHIATRIC DIRECTOR

Internationally based rehabilitation and health planning agency in New York City seeks upwardly mobile, flexible and creative Board eligible (or certified) **psychiatrist** for high level administrative position. Candidates must be able to travel. Duties include supervision of 500 in-resident patients in 5 states, program design, and the articulation of health care issues for purposes of social change. Salary is $50,000 plus fringe. We are interested in hiring for this position as quickly as possible. Please send resume to Ms. Shirley Lewkowitz, Odyssey Institute, Mabon Building 13, Wards Island, N.Y., N.Y. 10035.

FACULTY PSYCHIATRIST

Department of Psychiatry, University of Utah College of Medicine. Inpatient work with general psychiatric and forensic population. Twenty percent free time for research. Primary location at Utah State Hospital, one hours drive from University. Salary to start: $45,468 board eligible; $48,731 board certified. Plus approx. $2,200 per year deposited in retirement fund. Plus large benefit package. Spectacular mountain country with year-round recreation, within one hour of four major ski resorts. Near two major universities. Apply to David Tomb, M.D., University of Utah College of Medicine, Salt Lake City, UT 84132

©1978, Pfizer Inc.

Artist Leonard Leff uses sculpture to express the painful depression he once experienced. He remembers it as "a lowering of the flame of life. My energies ebbed, my will to live decreased, and I found myself retreating from the activities of life to a more introverted existence."

WHEN DEPRESSION EXPRESSES ITSELF

SINEQUAN®
(DOXEPIN HCl)

ANTIDEPRESSANT EFFECTIVENESS with convenient once-a-day *h.s.* dosage*

150-MG CAPSULE†

Also available in:
100-mg, 75-mg, 50-mg, 25-mg, 10-mg CAPSULES and ORAL CONCENTRATE, 10 mg/ml, in 120-ml (4-oz) bottles

*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.

† The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

ANTIDEPRESSANT EFFECTIVENESS

SINEQUAN® (DOXEPIN HCl)

150-mg CAPSULE*

CONVENIENT ONCE-A-DAY *h.s.* DOSAGE

which may improve patient compliance. The total daily dosage, up to 150 mg per day, may be given on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

USUALLY WELL TOLERATED

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have been reported occasionally. Drowsiness is the most commonly observed side effect. Dry mouth, blurred vision, constipation and urinary retention have been reported.

EXTENDED RANGE OF DOSAGE STRENGTHS

for flexibility in individualizing therapy.

*The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. These disorders should be ruled out, particularly in older patients. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN (doxepin HCl) in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Usage with Alcohol: It should be borne in mind that alcohol ingestion may increase the danger inherent in any intentional or unintentional SINEQUAN overdosage. This is especially important in patients who may use alcohol excessively.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy. Prescriptions should be written for the smallest feasible amount.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severity, a starting daily dose of 75 mg is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg/day to 150 mg/day.

In more severely ill patients higher doses may be required with subsequent gradual increase t 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying organi disease, lower doses may suffice. Some of these patients have been controlled on doses as lo as 25-50 mg/day.

The total daily dosage of SINEQUAN (doxepin HCl) may be given on a divided or once-a-da dosage schedule. If the once-a-day schedule is employed the maximum recommended dose 150 mg/day. This dose may be given at bedtime. **The 150 mg capsule strength is intended fo maintenance therapy only and is not recommended for initiation of treatment.**

Antianxiety effect is apparent before the antidepressant effect. Optimal antidepressant effec may not be evident for two to three weeks.

Overdosage.

A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias an tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileus hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressi supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorbe The use of activated charcoal has been recommended, as has been continuous gastric lavag with saline for 24 hours or more. An adequate airway should be established in comatose patien and assisted ventilation used if necessary. EKG monitoring may be required for several day since relapse after apparent recovery has been reported. Arrhythmias should be treated with th appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and CN symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow intr venous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine rapidly metabolized, the dosage should be repeated as required. Convulsions may respond standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depre sion. Dialysis and forced diuresis generally are not of value in the management of overdosag due to high tissue and protein binding of SINEQUAN.

Supply. SINEQUAN is available as capsules containing doxepin HCl equivalent to: 10 mg, 75 m and 100 mg doxepin: bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). 25 mg a 50 mg doxepin: bottles of 100, 1000, 5000, and unit-dose packages of 100 (10 x 10's). 150 m doxepin: bottles of 50, 500, and unit-dose packages of 100 (10 x 10's). SINEQUAN O Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibrat at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 10 m doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted w approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a number carbonated beverages. For those patients requiring antidepressant therapy who are methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mix together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not w grape juice. Preparation and storage of bulk dilutions is not recommended.

ADRIFT IN A SEA OF CONFUSING VOICES

'STELAZINE' HELPS FIND THE WAY BACK

The schizophrenic patient is often surrounded by confusing voices, bewildering thoughts, fright and anxiety. For such patients, 'Stelazine' provides effective, unsurpassed control of these and other psychotic symptoms.

Also important, convenient b.i.d. 'Stelazine' usually does not cause excessive sedation, which means that 'Stelazine' works with and not against your therapeutic program.

After 18 years of extensive research and clinical experience, no other antipsychotic agent has demonstrated significantly greater overall effectiveness and significantly fewer side effects than 'Stelazine'. These facts make 'Stelazine' a first choice for therapy.

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Generally avoid using in patients hypersensitive (e.g., blood dyscrasias, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only), 10 mg./ml.

TRIFLUOPERAZINE HCl.

A First Choice for Therapy

PERTOFRANE
(desipramine HCl)

he antidepressant o turn to...

▸ when the first tricyclic fails

"As amitriptyline and desipramine represent the extremes of the differences among the tricyclics, many clinicians start treatment with one or the other and then follow with the alternative drug if response to the first was unsatisfactory."[1]

▸ when side effects are a problem

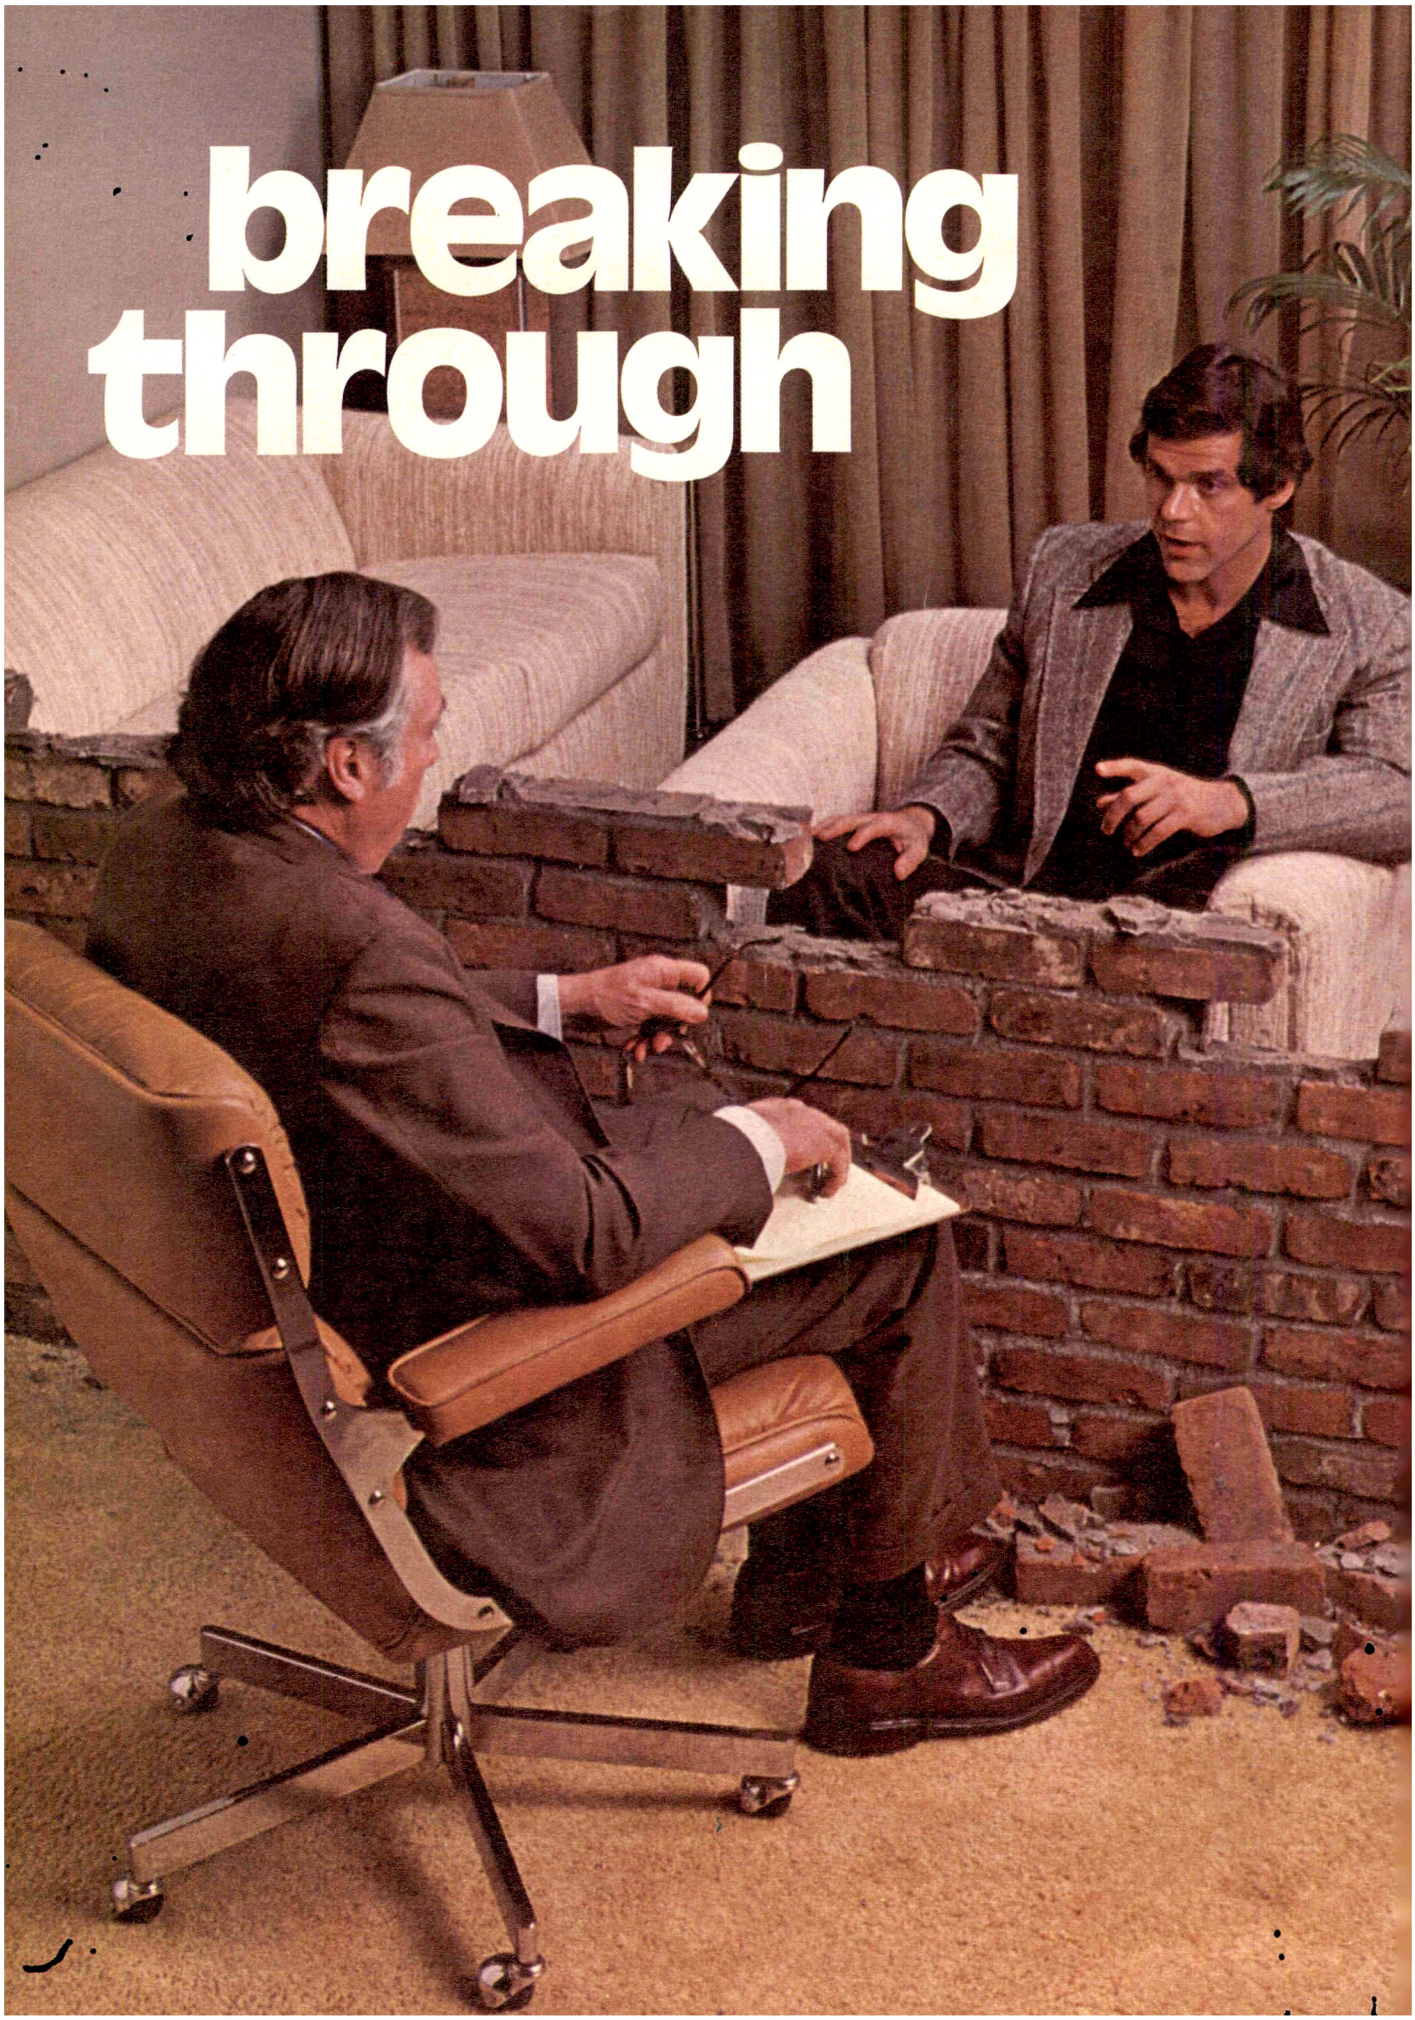
"Desipramine might be more appropriate for patients who are sensitive to anticholinergic effects or in whom sedative action is not desirable."[2]

▸ when activity is important

"Desipramine seems ideally suited to use in an active ambulatory patient population..."[3]

References: 1. Hollister, L.E.: Treatment of depression with drugs, Ann. Intern. Med. 89:78, 1978. 2. Blackwell, B. et al.: Anticholinergic activity of two tricyclic antidepressants, Am. J. Psychiatry 135:722, 1978. 3. Barnes, R. J.: Clinical depression: Double-blind study of desipramine and amitriptyline in depressive neurosis, Scientific Exhibit, Southern Medical Convention, Miami, Fla., Nov. 16-19, 1975.

PERTOFRANE® *(desipramine HCl)*



when the first tricyclic fails

Indication: For relief of mental depression. **Contraindications:** Do not use MAO inhibitors concomitantly or within 2 weeks of the use of this drug. Hyperpyretic crises or severe convulsive seizures may occur with such combinations; potentiation of adverse reactions can be serious or even fatal. When substituting Pertofrane (desipramine HCl) in patients receiving an MAO inhibitor, allow an interval of at least 14 days. Initial dosage in such patients should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated following recent myocardial infarction and in patients with a known hypersensitivity to tricyclic antidepressants. **Warnings:** Activation of psychosis may occasionally be observed in schizophrenic patients. Due to atropine-like effects and sympathomimetic potentiation, use only with the greatest care in patients with narrow-angle glaucoma or urethral or ureteral spasm. Do not use in patients with the following conditions unless the need outweighs the risk: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (may lower seizure threshold). This drug may block the action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents. Hypertensive episodes have been observed during surgery. The concurrent use of other central nervous system drugs or alcohol may potentiate adverse effects. Since many such drugs may be used during surgery, desipramine should be discontinued prior to elective procedures. The potentiation resulting from excessive use of alcohol may increase the danger inherent in a suicide attempt or overdosage. Caution patients on the possibility of impaired ability to operate a motor vehicle or dangerous machinery. Do not use in women who are or may become pregnant, or in children under 12 years of age, unless the clinical situation warrants the potential risk. Because of increased sensitivity to the drug, use lower than normal dosage in adolescent and geriatric patients. **Precautions:** Potentially suicidal patients require careful supervision and protective measures during therapy. Prescriptions should be limited to small quantities. Discontinuation of the drug may be necessary in the presence of increased agitation and anxiety shifting to hypomanic or manic excitement. Atropine-like effects may be more pronounced (e.g. paralytic ileus) in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents). Prescribe cautiously in hyperthyroid patients and in those receiving thyroid medications; transient cardiac arrhythmias have occurred in rare instances. Periodic blood and liver studies should supplement careful clinical observations in all patients undergoing extended courses of therapy. **Adverse Reactions:** The following have been reported: *Nervous System:* dizziness, drowsiness, insomnia, headache, disturbed visual accommodation, tremor, unsteadiness, tinnitus, paresthesias, changes in EEG patterns, epileptiform seizures, mild extrapyramidal activity, falling and neuromuscular incoordination. A confusional state (with such symptoms as hallucinations and disorientation), particularly in older patients and at higher dosage, may require discontinuation of the drug. *Gastrointestinal Tract:* anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea. *Skin:* skin rashes (including photosensitization), perspiration and flushing sensations. *Liver:* rare cases of transient jaundice (apparently of an obstructive nature) and liver damage. If jaundice or abnormalities in liver function tests occur, discontinue the drug and investigate. *Blood Elements:* bone-marrow depression, agranulocytosis, thrombocytopenia and purpura. If these occur, discontinue the drug. Transient eosinophilia has been observed. *Cardiovascular System:* orthostatic hypotension and tachycardia. Carefully supervise patients requiring concomitant vasodilating therapy, particularly during initial phases. *Genitourinary System:* urinary frequency or retention and impotence. *Endocrine System:* occasional hormonal effects, including gynecomastia, galactorrhea and breast enlargement, and decreased libido and estrogenic effect. *Sensitivity:* urticaria and rare instances of drug fever and cross-sensitivity with imipramine. **Dosage:** All patients except geriatric and adolescent: 75 to 150 mg./day in divided doses or as single daily dose. Dosage may be increased up to 200 mg. daily. Geriatric and adolescent patients should usually be started with lower dosage (25 to 50 mg. daily) and may not tolerate higher doses. Dosage may be increased up to 100 mg. daily. Lower maintenance dosages should be continued for at least 2 months after obtaining a satisfactory response. Therapy may be given in divided doses or as a single daily dose. **How Supplied:** 25 mg. capsules (pink), bottles of 100 and 1000. Also, 50 mg. capsules (maroon and pink), bottles of 100 and 1000.

USV LABORATORIES

USV Laboratories Inc.
Manati, P.R. 00701

breaking through

In marked agitation with depression symptomatic relief may make the patient more accessible and responsive.

Rapid relief of marked agitation in many patients
The tranquilizer component alleviates symptoms of agitation and anxiety within a few days, without apparent dulling of mental acuity. Hypnotic effects from the tranquilizer component appear to be minimal, particularly in patients permitted to remain active. However, TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks.

Highly effective antidepressant action
The antidepressant component relieves symptoms of depression such as poor concentration and feelings of hopelessness as well as early morning awakening; adequate relief of symptoms may take a few weeks or even longer.

Helps break barriers to psychotherapy
As symptoms are relieved, many patients often communicate more effectively, become more cooperative, and are able to return to normal daily activities.

More prescribing convenience
There are now *five* tablet strengths of TRIAVIL for ease of dosage adjustment. For many patients with agitation and depression, you can now initiate therapy with one TRIAVIL® 4-50, containing 4 mg perphenazine and 50 mg amitriptyline HCl, b.i.d. The regimen is simple, economical, and may well enhance patient compliance.

Treatment with TRIAVIL—a balanced view:
TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to overdosage of other drugs or mask other disorders. The possibility of suicide in depressed patients remains until significant remission occurs. Such patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

For marked
agitation with depression

dual-action
Triavil®

containing perphenazine and amitriptyline HCl

MSD
MERCK
SHARP &
DOHME

Copyright © 1979 by Merck & Co., Inc.

Please see following page for a brief summary of prescribing information.

More dosage strengths than any other formulation containing a tranquilizer and an antidepressant

dual-action Triavil®

containing perphenazine and amitriptyline HCl

Available:
TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-50: Each tablet contains
4 mg perphenazine and 50 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl.

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides. There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to perphenazine and other antipsychotic drugs is not known.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.
Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) have been reported and can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw. Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. Fine vermicular movements of the tongue may be an early sign of the syndrome. The full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; other adverse reactions reported with various phenothiazine compounds, but not with perphenazine, include grand mal convulsions, cerebral edema, polyphagia, pigmentary retinopathy, photophobia, skin pigmentation, and failure of ejaculation.

The phenothiazine compounds have produced blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur after long-term administration of some phenothiazines. Although it has not been reported in patients receiving TRIAVIL, the possibility that it might occur should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia have also been reported.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs and must be considered when amitriptyline is administered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states disturbed concentration; disorientation; delusions; hallucinations; excitement anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth blurred vision; disturbance of accommodation; increased intraocular pressure constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness, weakness; fatigue; headache; weight gain or loss increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

Tranxene® (CLORAZEPATE DIPOTASSIUM) 4306CB

CAPSULES,
SINGLE DOSE TABLETS
Brief Summary

ACTIONS — Pharmacologically, clorazepate dipotassium has the characteristics of the benzodiazepines. It has depressant effects on the central nervous system. The primary metabolite, nordiazepam, quickly appears in the blood stream. The serum half-life is about 2 days. The drug is metabolized in the liver and excreted primarily in the urine. (See CLINICAL PHARMACOLOGY section.)

INDICATIONS — TRANXENE is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

TRANXENE is indicated for the symptomatic relief of acute alcohol withdrawal.

The effectiveness of TRANXENE in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

CONTRAINDICATIONS — TRANXENE is contraindicated in patients with a known hypersensitivity to the drug, and in those with acute narrow angle glaucoma.

WARNINGS — TRANXENE is not recommended for use in depressive neuroses or in psychotic reactions.

Patients on TRANXENE should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles.

Since TRANXENE has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, and cautioned that the effects of alcohol may be increased.

Because of the lack of sufficient clinical experience, TRANXENE is not recommended for use in patients less than 18 years of age.

Physical and Psychological Dependence:

Withdrawal symptoms (similar in character to those noted with barbiturates and alcohol) have occurred following abrupt discontinuance of clorazepate. Symptoms of nervousness, insomnia, irritability, diarrhea, muscle aches and memory impairment have followed abrupt withdrawal after long-term use of high dosage.

Caution should be observed in patients who are considered to have a psychological potential for drug dependence.

Evidence of drug dependence has been observed in dogs and rabbits which was characterized by convulsive seizures when the drug was abruptly withdrawn or the dose was reduced; the syndrome in dogs could be abolished by administration of clorazepate.

Usage in Pregnancy:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. TRANXENE, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.

Usage during Lactation:

TRANXENE should not be given to nursing mothers since it has been reported that nordiazepam is excreted in human breast milk.

PRECAUTIONS — In those patients in which a degree of depression accompanies the anxiety, suicidal tendencies may be present and protective measures may be required. The least amount of drug that is feasible should be available to the patient.

Patients on TRANXENE for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

ADVERSE REACTIONS — The side effect most frequently reported was drowsiness. Less commonly reported (in descending order of occurrence) were: dizziness, various gastrointestinal complaints, nervousness, blurred vision, dry mouth, headache, and mental confusion. Other side effects included insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression and slurred speech.

There have been reports of abnormal liver and kidney function tests and of decrease in hematocrit.

Decrease in systolic blood pressure has been observed.

DOSAGE AND ADMINISTRATION

For the symptomatic relief of anxiety:

TRANXENE is administered orally. The capsules may be given in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 15 to 60 mg. daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a daily dose of 7.5 to 15 mg.

TRANXENE capsules may also be administered as a single dose daily at bedtime; the recommended initial dose is 15 mg. After the initial dose, the response of the patient may require adjustment of subsequent dosage. Lower doses may be indicated in the elderly patient. Drowsiness may occur at the initiation of treatment and with dosage increment.

TRANXENE-SD tablets (22.5 mg.) may be administered as a single dose every 24 hours. This tablet is intended as an alternate dosage form for the convenience of patients stabilized on a dose of 7.5 mg. capsules three times a day. TRANXENE-SD tablets should not be used to initiate therapy.

TRANXENE-SD HALF STRENGTH tablets (11.25 mg.) may be administered as a single dose every 24 hours.

For the symptomatic relief of acute alcohol withdrawal:

Recommended schedule: 1st 24 hours, 30 mg. TRANXENE initially, followed by 30 to 60 mg. in divided doses; 2nd 24 hours, 45 to 90 mg. in divided doses; 3rd 24 hours, 22.5 to 45 mg. in divided doses; 4th day, 15 to 30 mg. in divided doses. Thereafter gradually reduce to 7.5 to 15 mg. daily, and discontinue as soon as condition is stable. Maximum daily dose is 90 mg. Avoid excessive reductions in total drug on successive days.

DRUG INTERACTIONS — If TRANXENE is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. Animal experience indicates that TRANXENE prolongs the sleeping time after hexobarbital or after ethyl alcohol, increases the inhibitory effects of chlorpromazine, but does not exhibit monoamine oxidase inhibition. Clinical studies have shown increased sedation with concurrent hypnotic medications. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If TRANXENE is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

MANAGEMENT OF OVERDOSAGE — Overdosage is usually manifested by varying degrees of CNS depression ranging from slight sedation to coma. As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

There are no specific antidotes for the benzodiazepines. The treatment of overdosage should consist of the general measures employed in the management of overdosage of any CNS depressant. Gastric evacuation either by the induction of emesis, lavage, or both, should be performed immediately. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though rarely reported, may occur with large overdoses. In such cases the use of agents such as Levophed® (levarterenol) or Aramine® (metaraminol) should be considered.

While reports indicate that individuals have survived overdoses of TRANXENE (clorazepate dipotassium) as high as 450 to 675 mg., these doses are not necessarily an accurate indication of the amount of drug absorbed since the time interval between ingestion and the institution of treatment was not always known. Sedation in varying degrees was the most common physiological manifestation of TRANXENE overdosage. Deep coma when it occurred was usually associated with the ingestion of other drugs in addition to TRANXENE.

CLINICAL PHARMACOLOGY — Studies in healthy men have shown that TRANXENE has depressant effects on the central nervous system. Prolonged administration of single daily doses as high as 120 mg. was without toxic effects. Abrupt cessation of high doses was followed in some patients by nervousness, insomnia, irritability, diarrhea, muscle aches, or memory impairment.

Absorption — Excretion:

After oral administration of TRANXENE, there is essentially no circulating parent drug. Nordiazepam, its primary metabolite, quickly appears in the blood stream. In 2 volunteers given 15 mg. (50 μC) of ^{14}C-TRANXENE, about 80% was recovered in the urine and feces within 10 days. Excretion was primarily in the urine with about 1% excreted per day on day 10.

HOW SUPPLIED — TRANXENE (clorazepate dipotassium) is supplied as capsules in three dosage strengths:

3.75 mg. capsules (gray with white cap) in bottles of 100 (NDC 0074-3417-13) and 500 (NDC 0074-3417-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3417-11).

7.5 mg. capsules (gray with maroon cap) in bottles of 30 (NDC 0074-3418-30), 100 (NDC 0074-3418-13) and 500 (NDC 0074-3418-53). Also available in ABBO-PAC unit dose packages of 100 capsules (NDC 0074-3418-11).

15 mg. capsules (all gray) in bottles of 100 (NDC 0074-3419-13) and 500 (NDC 0074-3419-53). Also available in ABBO-PAC unit dose packages of 100 capsules (NDC 0074-3419-11).

TRANXENE-SD single dose tablets are supplied in two dosage strengths:

TRANXENE-SD 22.5 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-2997-13).

TRANXENE-SD HALF STRENGTH 11.25 mg. tablets (blue-colored) in bottles of 30 (NDC 0074-2699-30) and 100 (NDC 0074-2699-13).

Awake on the job, yet anxiety controlled

Troublesome drowsiness uncommon. Tranxene lets you manage anxiety in most patients without problem sedation. Any initial drowsiness is usually transient. By avoiding excessive sedation, Tranxene helps you calm patients without compromising their capacities.*

ADRIFT IN A SEA OF CONFUSING VOICES

'STELAZINE' HELPS FIND THE WAY BACK

The schizophrenic patient is often surrounded by confusing voices, bewildering thoughts, fright and anxiety. For such patients, 'Stelazine' provides effective, unsurpassed control of these and other psychotic symptoms.

Also important, convenient b.i.d. 'Stelazine' usually does not cause excessive sedation, which means that 'Stelazine' works with and not against your therapeutic program.

After 18 years of extensive research and clinical experience, no other antipsychotic agent has demonstrated significantly greater overall effectiveness and significantly fewer side effects than 'Stelazine'. These facts make 'Stelazine' a first choice for therapy.

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Generally avoid using in patients hypersensitive (e.g., blood dyscrasias, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only), 10 mg./ml.

A First Choice for Therapy

Increase your professional library—order APA's three most recent Task Force Reports now

Electroconvulsive Therapy, Task Force Report 14

Prepared by the APA Task Force on Electroconvulsive Therapy; Fred Frankel M.D., Chairperson

This new report presents a comprehensive study of one of the most controversial issues in psychiatry today. The efficacy of ECT for affective disorders, schizophrenia, and for other mental illnesses is discussed, as are its adverse effects. Chapters included contain information on the social, ethical, and legal aspects of ECT; the methods of its administration and the training and education which the use of it requires; and its physiological and biochemical concomitants. Possible future research is also discussed.

The History of American Psychiatry: A Teaching and Research Guide, Task Force Report 15

Prepared by the APA Committee on History, Library, and Museum; Daniel Blain, M.D. and Michael Barton, Ph.D.

This report presents a compilation of reading and resource materials related to the history of the science of psychiatry and the learning and teaching of its historic development. Attention is given to the actions of citizens, professionals and government which have affected this historical development, and a chronology of psychiatry (primarily in the United States) is included.

Relating Environment to Mental Health and Illness: The Ecopsychiatric Base, Task Force Report 16

Prepared by the APA Task Force on the Ecopsychiatric Data Base; Jay T. Shurley, M.D., Chairperson

This report details the work of the Task Force in giving a conceptual framework to the linkage of environment with mental health and illness. A comprehensive bibliography, sections of which are annotated, is given.

Information for Contributors

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material, have not been published previously, and are not being considered for publication elsewhere. Papers with multiple authors are reviewed with the assumption that all authors have approved them.

Copyright

The *Journal* requires express transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. All submissions must be accompanied by a cover letter *signed by all authors* and using the following wording:

In consideration of the *American Journal of Psychiatry*'s taking action in reviewing and editing my submission [include title here] the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the American Psychiatric Association in the event that such work is published by the American Psychiatric Association.

Work done as part of an individual's duties as a federal employee is in the public domain. The cover letter in such cases should contain the following wording and should be signed by all authors:

The work described in [include title here] was done as part of my (our) employment with the federal government and is therefore in the public domain.

In addition, authors must obtain letters of permission from publishers for use of extensive quotations (more than 500 words) and of tables and figures that originally appeared elsewhere.

Patient Anonymity

Ethical as well as legal considerations require careful attention to the protection of a patient's anonymity in case reports and elsewhere. Identifying information such as names, initials, hospital numbers, and dates must be avoided. In addition, authors should disguise identifying information about a patient's characteristics and personal history.

Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained.

Review Process

Papers are reviewed by at least two experts to determine the originality, validity, and significance of content and conclusions. Authors will usually be advised within 2–3 months of the decision on their paper, although delays are sometimes unavoidable. Reviewers' comments will be returned with rejected manuscripts if they are judged to be useful to the authors. All reviewers remain anonymous.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. All correspondence will be sent to the first-named author unless otherwise specified. Papers that are not accompanied by the appropriate cover letter, including the copyright transfer statement, will not be reviewed until such a statement is received.

Authors will be notified as soon as possible of the receipt of their paper; at this time, the paper will be assigned a number that must be included in all further correspondence. It is imperative that authors of papers under consideration notify the *Journal* of changes of address.

Annual Meeting Papers

The *Journal* has first refusal rights for numbered papers accepted for presentation at the Association's annual meetings. Authors of annual meeting papers should follow instructions they will receive in a letter from the Editor before the meeting. Annual meeting papers may be submitted for review before the meeting only if they are in *final form*, i.e., are ready for review. Authors must *not* submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. These papers are subject to the same peer review criteria as other submissions, and not all papers can be published in the *Journal*. Authors who wish to submit their papers elsewhere must secure permission from the Editor. The *Journal* will assign its own number to each paper received for review; this number must appear in any further communications about the paper. The copyright transfer statement described above must accompany annual meeting papers submitted for review.

Length

The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles—3,800 words or the equivalent, including references, tables, and figures (about 15 manuscript pages). Brief Communications—2,500 words or equivalent (about 10 manuscript pages). Clinical and Research Reports—1,000 words, 10 references, 1 table (no figures can be used in this section). Letters to the Editor—500 words, 5 references. The number of words, tables, and figures should be noted on the title page.

TYPES OF ARTICLES

Overviews

Overview articles attempt to bring together important relevant information on a topic of general interest to psychiatry. They are usually written at the invitation of the Editor; authors who have ideas for overview articles are advised to check with the Editor to ensure that a similar work is not in preparation. Overviews should not exceed 25 double-spaced pages (about 7,500 words) and should have no more than 100 references. All overviews, including those written by invitation, are given the same peer review received by other papers.

Regular Articles and Brief Communications

The primary difference between these two types of papers is length. The "brief communication" designation does not imply less sophisticated or complete work: it merely means that the content can be expressed within the upper limit of 2,500 words. There is no difference in the review procedure or scheduling of these articles. Authors who submit unnecessarily long articles with redundancies and loose writing style will be asked to shorten them, which can delay publication. Authors should choose their words carefully, avoiding lengthy introductions containing material that is common knowledge, summaries that merely repeat the results, unnecessary tables, figures or references, etc. Single case reports will not be accepted as regular articles or Brief Communications; these papers should be submitted as Clinical and Research Reports.

Clinical and Research Reports

This section contains very brief articles (maximum of 1,000 words, 10 references, 1 table, and *no figures*) reporting new research findings, including preliminary data from pilot

studies, and case reports that 1) describe new syndromes, 2) cast a new light on established ones, 3) indicate a new therapeutic procedure of potential value, or 4) describe adverse effects or previously unreported complications of drugs or therapeutic interventions. Because of the stringent criteria for this section, authors can expect more rapid publication than is possible in other sections. Submitted papers that substantially exceed the stated maximum length or contain figures will be returned to the author unreviewed.

Prompt Publication Policy

Articles submitted for prompt publication can be of either regular or Brief Communication length (a "prompt publication policy" is automatically in effect for Clinical and Research Reports). These papers are given priority in scheduling; however, authors should be aware that the minimum publication time is four months. Prompt publication papers must meet stringent criteria of originality and be of major, immediate importance to the field. Authors must state their reasons for wanting rapid review in a cover letter to the Editor. It is important to think carefully about the nature of the paper before requesting prompt publication; a paper may be delayed if it is submitted inappropriately.

Other Sections

Letters to the Editor. Brief letters (maximum of 500 words and 5 references) will be considered if they include the notation "for publication" in the upper right corner. Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. The *Journal* is unable to notify authors of receipt of letters or to return those not published. All letters are subject to editing. Letters must be typed *double-spaced* throughout on letter-size bond paper; two copies are required. Letters that are not typed appropriately or do not conform to *Journal* reference style will be returned to the author for revision.

Book Reviews. Books for review or listing may be sent directly to the Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. Book reviews are usually solicited by the editor. Authors interested in reviewing a particular book are urged to contact the editorial office to see if the Editor wishes the book to be reviewed and to ascertain whether it has been previously assigned to another reviewer. Reviews are usually less than 500 words long, seldom contain references, and will be edited.

TYPING AND ARRANGING THE PAPER

All manuscripts must be typed in upper- and lowercase on one side only of 22 × 28 cm (8½ × 11 inches) *nonerasable* bond paper. All parts of the manuscript, including case reports, quotations, references, and tables, must be double-spaced throughout. All 4 margins must be 3¾ cm (1½ inches). The manuscript should be arranged in the following order, with each numbered item beginning a new page: 1) title page, 2) précis, 3) text, 4) references, 5) tables, 6) footnotes to text, and 7) figure captions. All pages must be numbered, with the title page as number 1. Please consult the following section on *Journal* style specifications for criteria for each part of the paper.

STYLE SPECIFICATIONS

Title Page

Title. The title should be informative but as brief as possible. Headline style (declarative sentences) should be avoided. Abbreviations and acronyms are rarely used.

By-line. Authors named in the by-line should be limited to principal researchers and/or writers; collaborators can be acknowledged in a footnote. Please include degrees (other than honorary or undergraduate) after the authors' names.

Previous presentation. If the paper has been presented orally, please give the name of the meeting, the place, and inclusive dates.

Author affiliations. The authors' position titles and affiliations should be given in a paragraph using complete sentences. A full address is necessary only for the author who is to receive reprint requests.

Acknowledgments. Acknowledgments should be in a separate paragraph on the title page. Grant support should include the full name of the granting agency as well as the grant number. Individual acknowledgments should be as brief as possible. Acknowledgments of companies that supplied drugs are used only in the case of experimental drugs or those unavailable in this country.

Other requirements. The number of words, tables, and figures should appear in the upper right corner and a phone number for the corresponding author in the lower right.

Précis

The précis should be up to 100 words for regular articles and Brief Communications (no précis is used in the Clinical and Research Reports section). The précis should be a single paragraph using complete, connected sentences, active verbs, and the third person. In most cases, the précis replaces a summary.

Text

Headings and subheadings should be inserted at reasonable intervals in all types of papers. Footnotes to text material should be typed on a separate page at the end of the manuscript. Summaries are rarely desirable, although a final "Comment" or "Conclusions" section may be used. The body of the paper should be written in the active voice and first person where appropriate.

Statistics. Authors should be sure that statistics used are both necessary and appropriate. Statistical tests should be described and a reference citation given if the tests are not generally known. It is not sufficient to say "differences between the groups were significant." In cases of lengthy complicated analyses, the authors may summarize results and indicate that details are available from them on request.

Abbreviations. All abbreviations (other than those for metric units) should be explained the first time they are used. Idiosyncratic abbreviations should be avoided: overuse of abbreviations may hinder rather than facilitate readability.

Drugs. Generic rather than trade names of drugs should be used; trade names may be given parenthetically if necessary.

Units of measurement. All measurements should be in metric units; standard abbreviations are used.

References

References should be restricted to closely pertinent material; a complete review of the literature is rarely desirable. *Accuracy of citation is the author's responsibility.* References should conform exactly to the original spelling, accents, punctuation, etc. Authors should be sure that all references listed have been cited in text; no bibliographies can be used.

References are numbered and listed by their order of appearance in text; the text citation is followed by the appropriate reference number in parentheses. Do *not* arrange the list alphabetically.

Personal communications, unpublished manuscripts, manuscripts submitted but not yet accepted, and similar unpublished items should not appear in the reference list. Such citations may be noted in text or in a footnote. It is the author's responsibility to obtain permission to refer to another individual's unpublished observations. Manuscripts that are actually "in press" may be cited as such in the reference list; the name of the journal must be included.

Type references in the style shown below and on the next page, double-spaced *throughout* (not just a line between

references). List up to three authors; designate one or more authors past the third "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*; journals not indexed there should not be abbreviated.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349-365, 1967
3. Gold PW, Goodwin FK: Urinary free cortisol in depression and mania. Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont, Canada, May 2-6, 1977
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968

Tables

Tables should be self-explanatory and should supplement rather than duplicate text. Authors may be asked to delete tables that present data which could be given succinctly in text or repeat information in the Results section. Tables are generally reserved for data presentation and not used as lists or charts. They should be no wider than 120 typewriter characters, including spaces. Consult recent issues of the *Journal* for table style. Please note that no vertical rules or internal horizontal rules are used. It is usually desirable to give both numbers and percentages where applicable. All units of measurement must be specified within the table. Metric measurements are used in tables and throughout the text. Each table should be identified numerically and include a concise title.

Figures

Figures should be used only for data that cannot be adequately presented in text or tabular form. Figures should be submitted as glossy prints with one photocopy attached to each manuscript copy. The author's name and the title of the paper should appear on a gummed label affixed to the back of each glossy. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Authors are urged to consider carefully the necessity of figures; they may be asked to delete figures that repeat information available in text. It is often advisable to obtain professional assistance in the preparation of figures.

PROCESSING OF ACCEPTED MANUSCRIPTS

Authors will be notified of acceptance of their papers; papers will then be edited and sent to the first-named (or corresponding) author for corrections and answers to editorial queries. No galley proofs are sent to authors, so the edited manuscript should be read with extreme care. Prompt return of edited manuscripts is essential. Authors who expect to be away from their offices for a long period or who change address after notification of acceptance should so inform the *Journal* office.

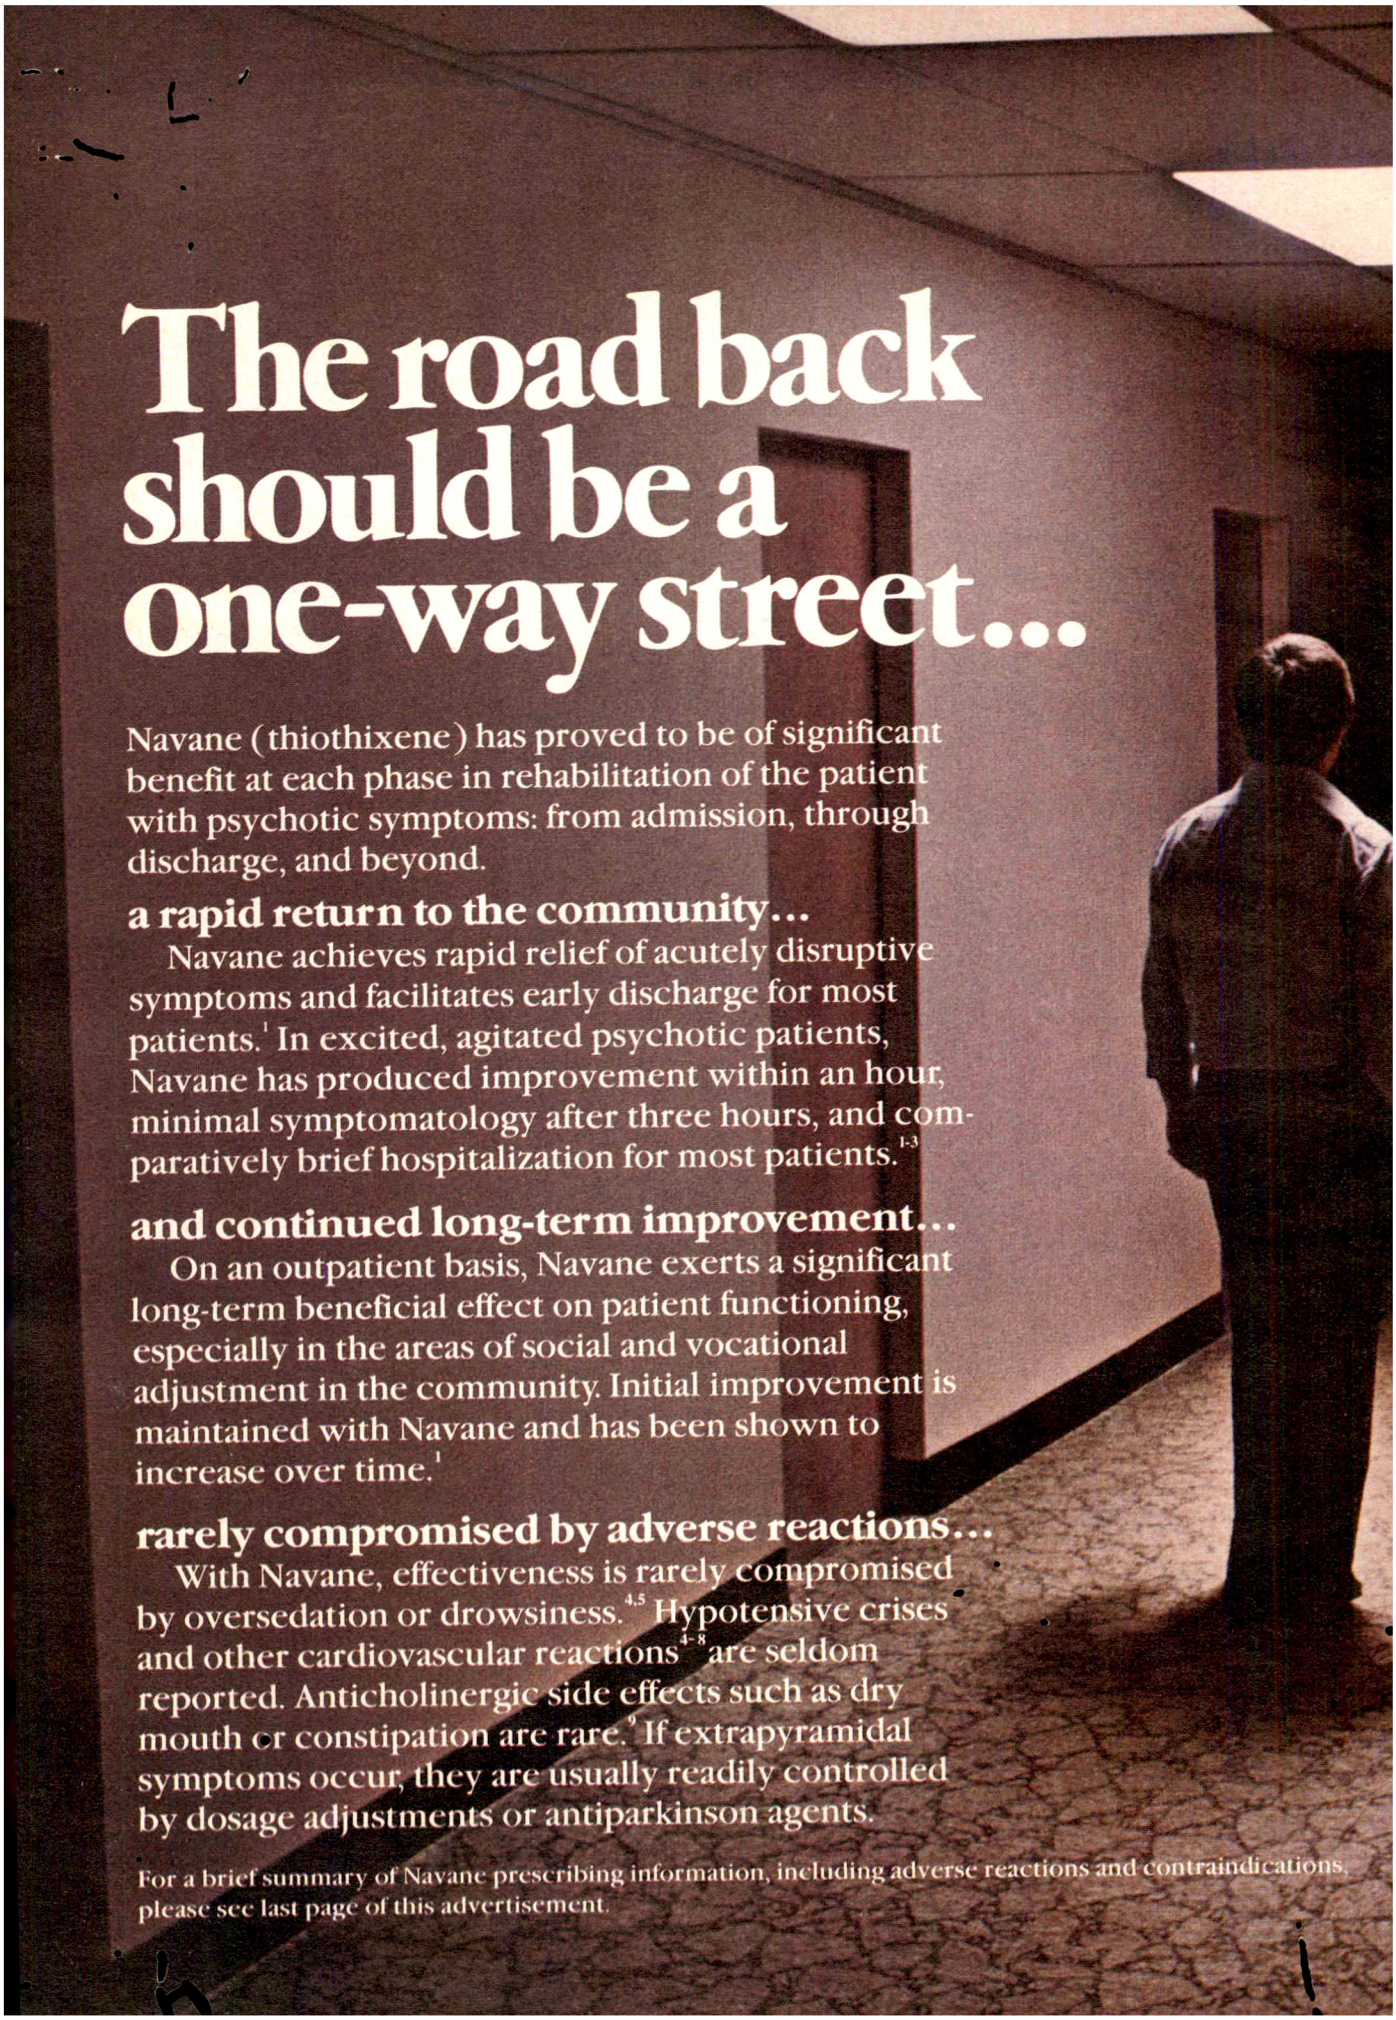
Manuscripts are accepted with the understanding that the Editor has the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style.

PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for such permission, except in cases of nonprofit use for educational purposes or of an author who wishes to reprint his/her own material. Requests will be facilitated if they are accompanied by written permission from the author of the material.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Reprint orders from others should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.



The July 1979 issue of

The American Journal of Psychiatry

will feature

- **Time, Age, and the Life Cycle**

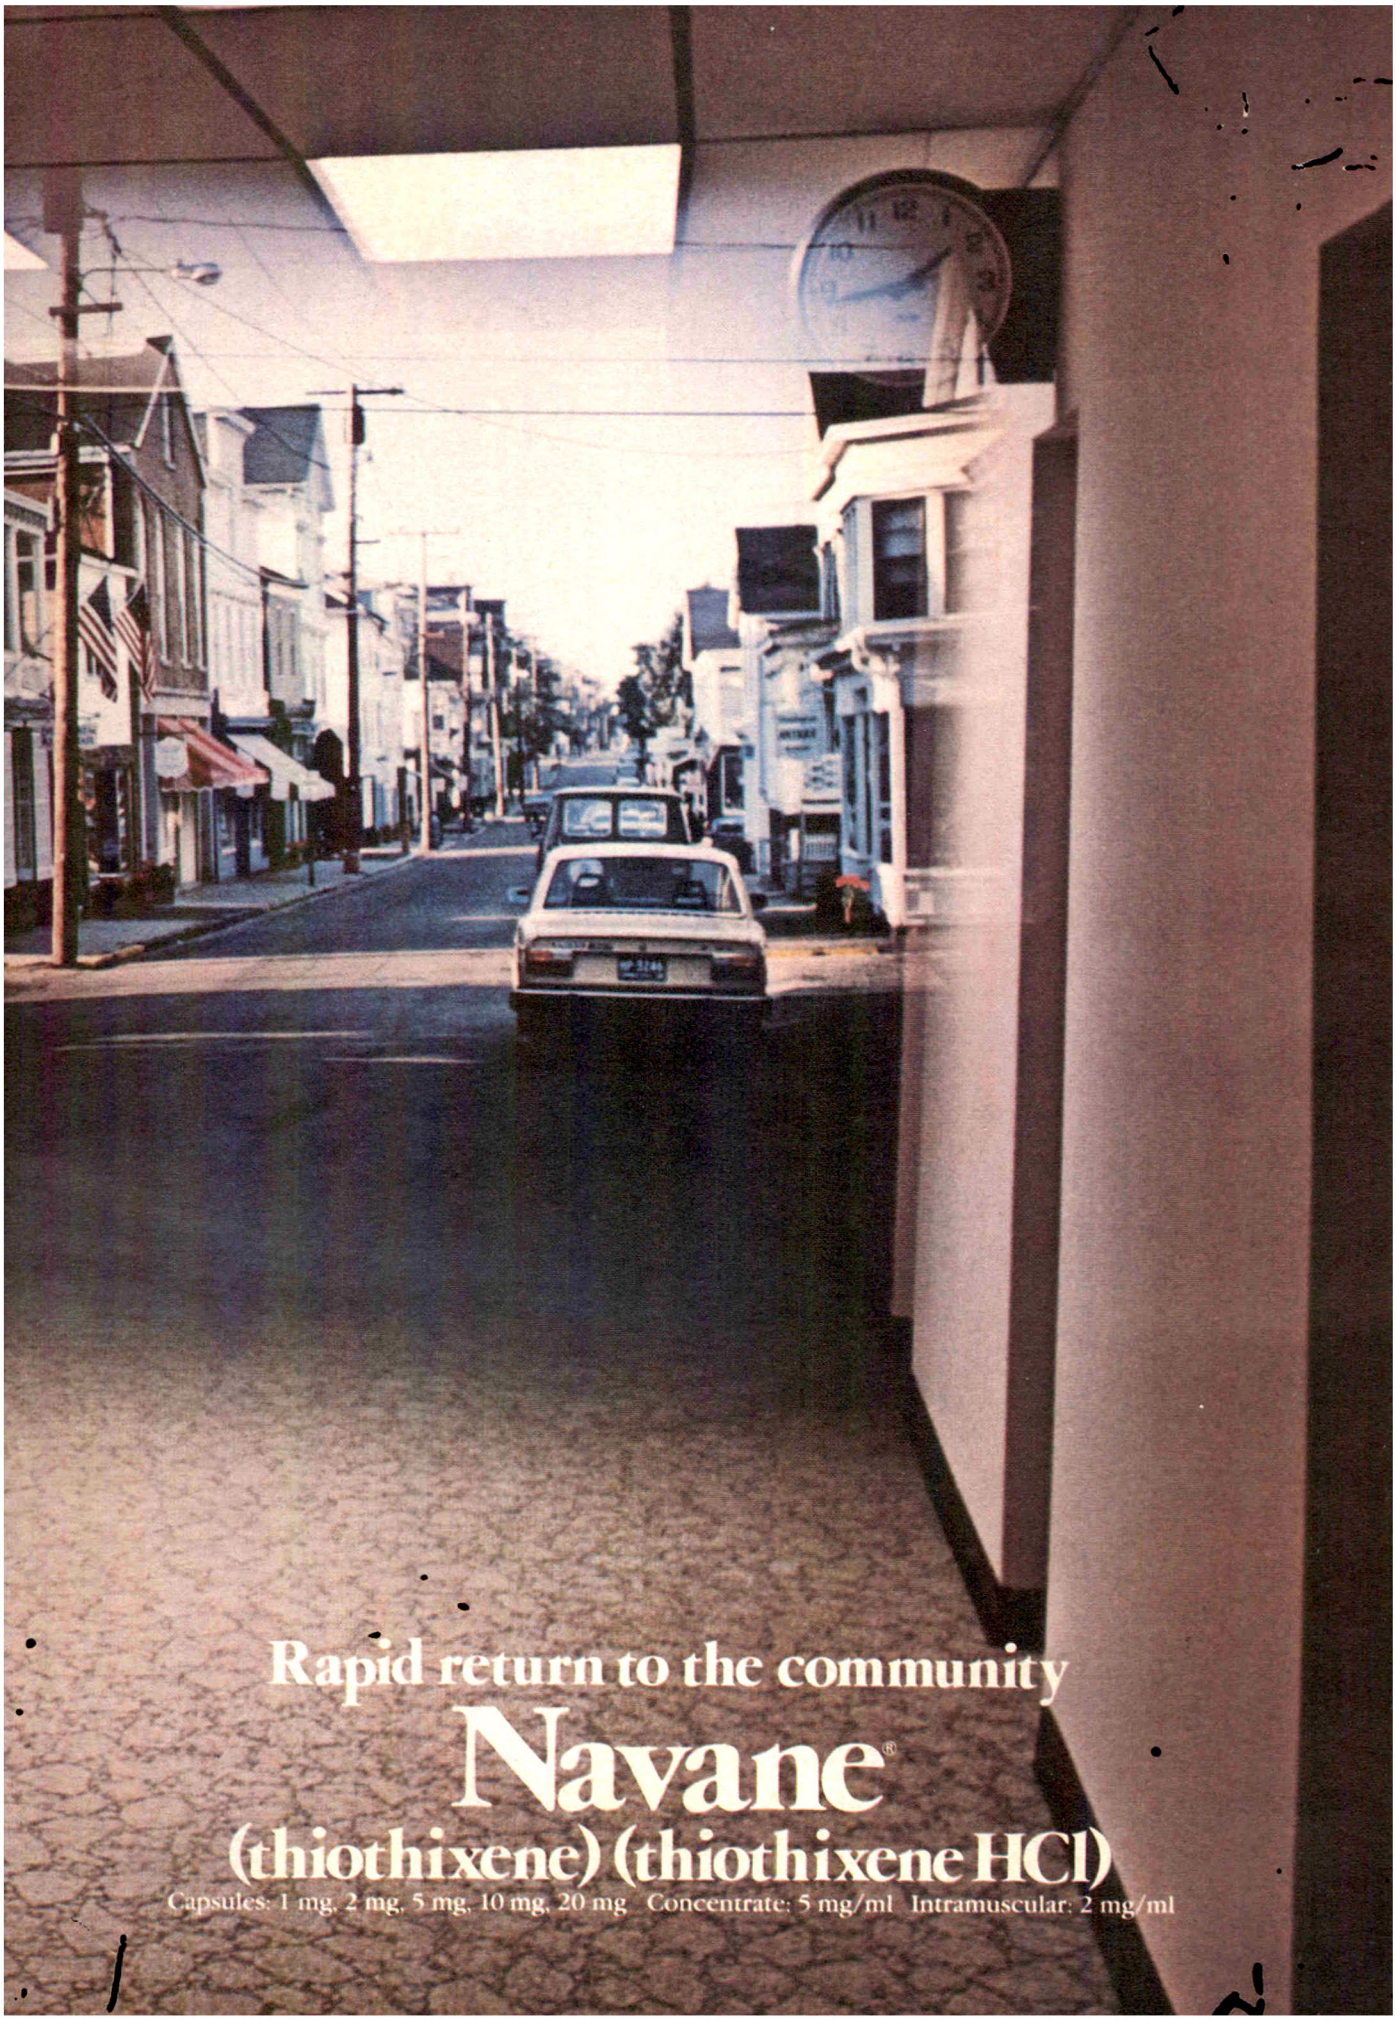
  By Bernice L. Neugarten

The road back should be a one-way street...

Navane (thiothixene) has proved to be of significant benefit at each phase in rehabilitation of the patient with psychotic symptoms: from admission, through discharge, and beyond.

a rapid return to the community...

Navane achieves rapid relief of acutely disruptive symptoms and facilitates early discharge for most patients.[1] In excited, agitated psychotic patients, Navane has produced improvement within an hour, minimal symptomatology after three hours, and comparatively brief hospitalization for most patients.[1-3]



and continued long-term improvement...

On an outpatient basis, Navane exerts a significant long-term beneficial effect on patient functioning, especially in the areas of social and vocational adjustment in the community. Initial improvement is maintained with Navane and has been shown to increase over time.[1]

rarely compromised by adverse reactions...

With Navane, effectiveness is rarely compromised by oversedation or drowsiness.[4,5] Hypotensive crises and other cardiovascular reactions[4-8] are seldom reported. Anticholinergic side effects such as dry mouth or constipation are rare.[9] If extrapyramidal symptoms occur, they are usually readily controlled by dosage adjustments or antiparkinson agents.

For a brief summary of Navane prescribing information, including adverse reactions and contraindications, please see last page of this advertisement.

Rapid return to the community
Navane®
(thiothixene) (thiothixene HCl)
Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

Rapid return to the community

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

BRIEF SUMMARY OF PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Contraindications. Navane (thiothixene) is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy*– Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration of Navane to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children– The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration– As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane (thiothixene). Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudo-parkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leukocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution–For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane (thiothixene) Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate– In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Stimulants that may cause convulsions (e.g. picrotoxin or pentylenetetrazol) should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg of thiothixene in bottles of 100, 1,000, and unit-dose pack of 100 (10 x 10's). Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100, 500, and unit-dose pack of 100 (10 x 10's).

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg, and in 30 ml (1 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, and 5 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10 vials. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

CHARLES C THOMAS · PUBLISHER

EARLY RECOLLECTIONS: Their Use in Diagnosis and Psychotherapy *compiled and edited by* **Harry A. Olson,** *Private Practice, Reisterstown, Maryland. Foreword by* **Raymond J. Corsini.** *(34 Contributors)* This book is both an exhaustive compendium of the literature and an up-to-date manual for the use of early recollections in diagnosis and psychotherapy. Contributions include specific techniques for the use of early recollections with children, to reduce unwanted feelings of clients, and to enhance vocational counseling. Retrieval and use of early recollections under hypnosis are also examined. A presentation of the complete Manaster-Perryman scoring manual is featured. *'79, 400 pp., 4 il., 10 tables, $27.50*

LAW, PSYCHOLOGY, AND THE COURTS: Rethinking Treatment of the Young and the Disturbed *by* **Ellsworth A. Fersch Jr.,** *Harvard Univ., Cambridge, Massachusetts.* Herein, the author provides authoritative, thought-provoking discussions on such topics as punishing young criminals, awarding of custody and facing ethical issues in court settings. Chapters are also included on handling young criminals and treatment in the court clinic setting. Readers will discover new ideas and perspectives in this book that will help them with professional pursuits related to law, psychology and the courts. *'79, 184 pp., 2 tables, $14.75*

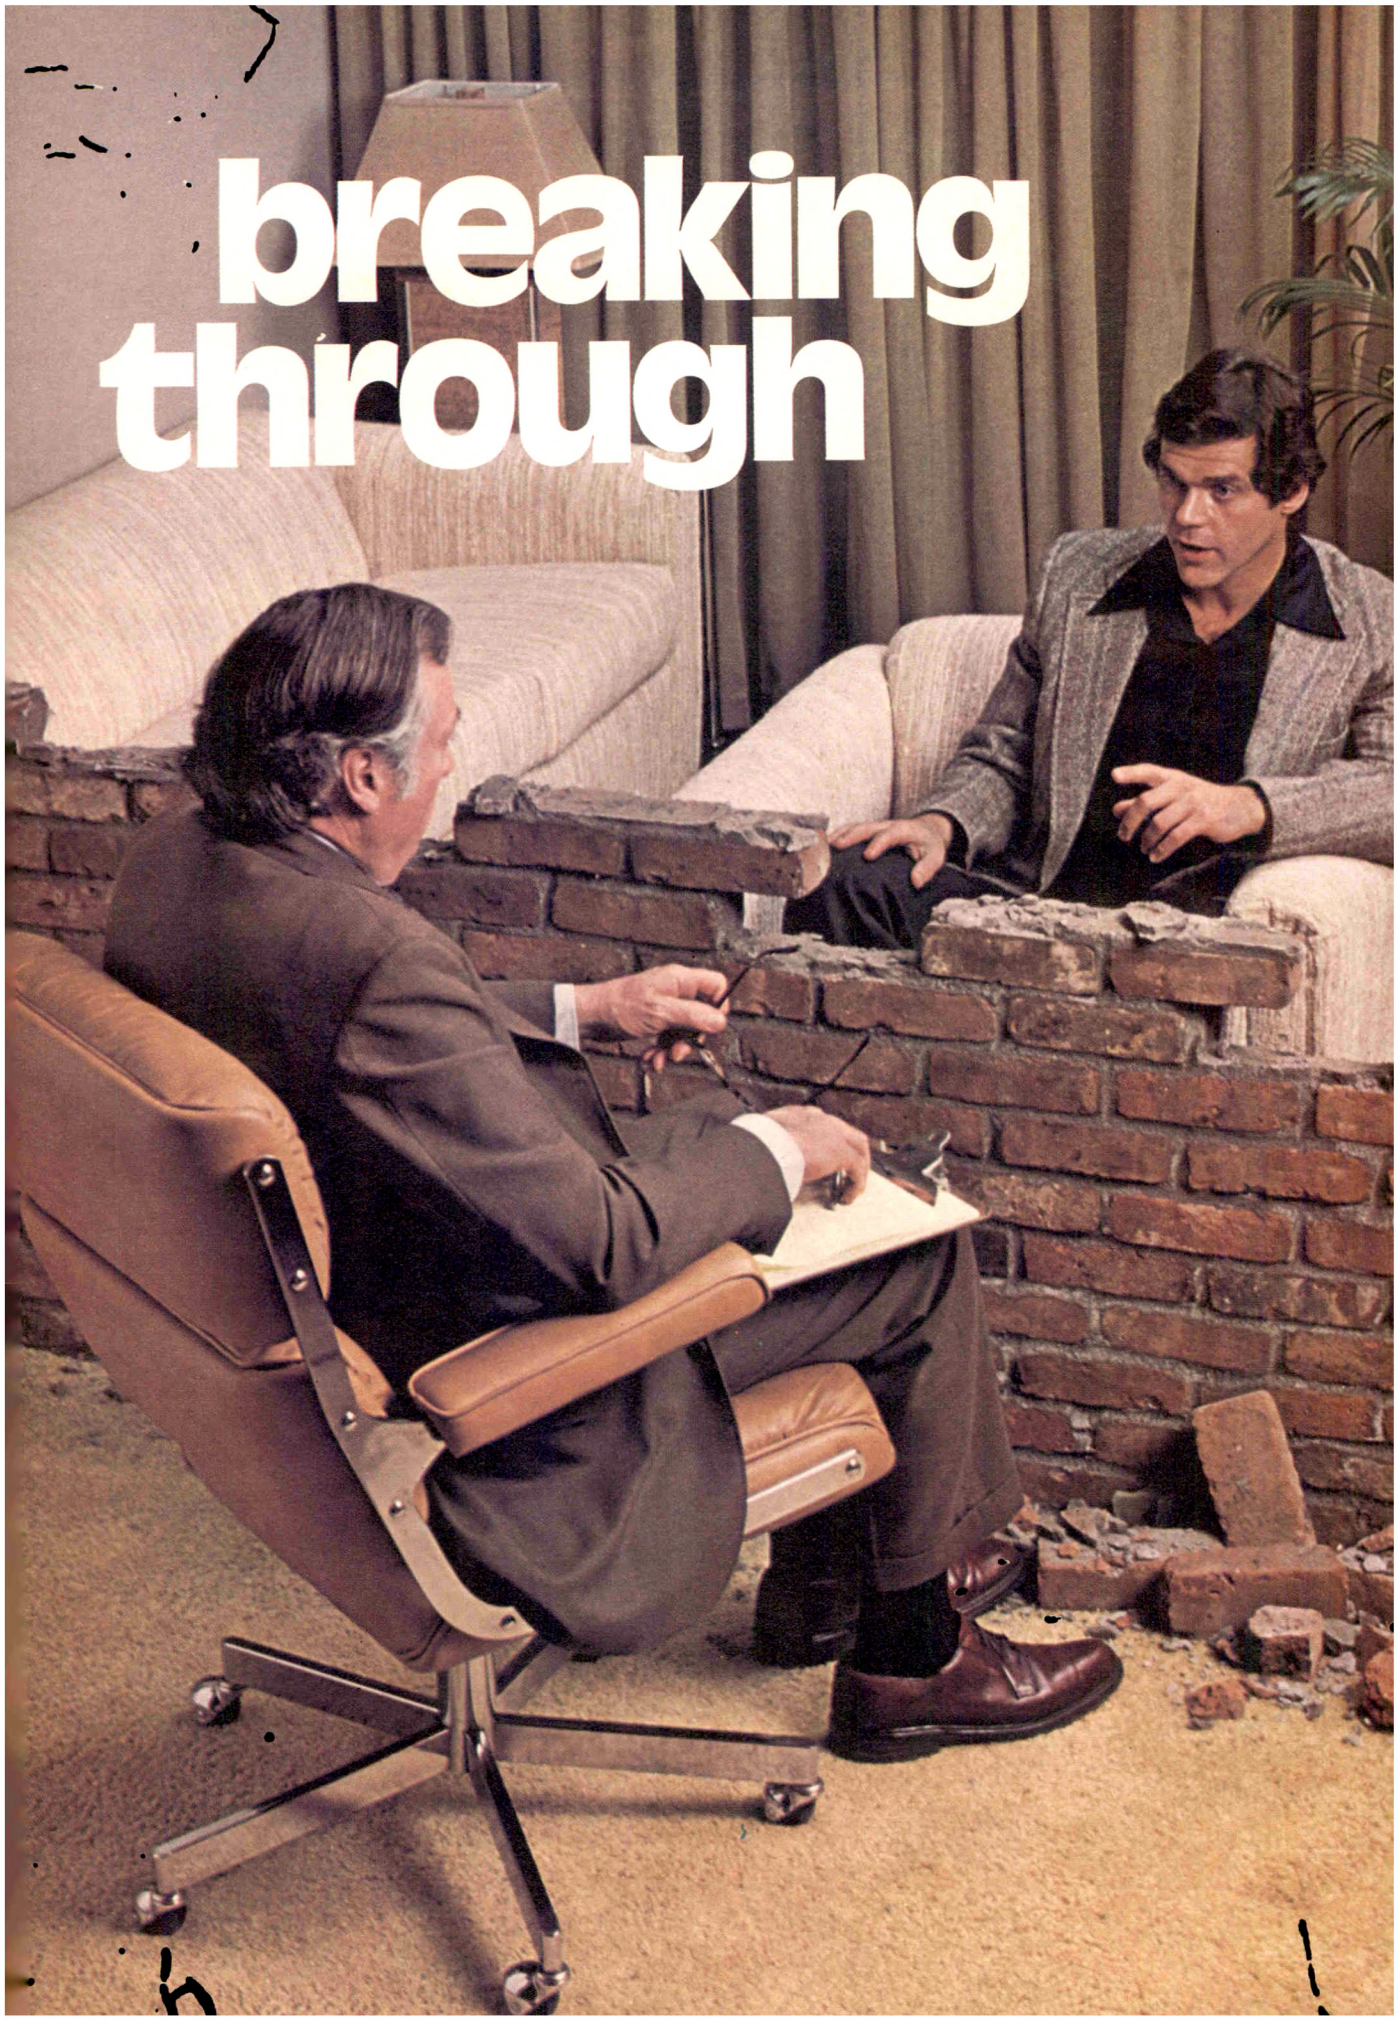
CLASSROOM MANAGEMENT: A Guide for the School Consultant *by* **Jack Tanaka,** *Institute for Juvenile Research, Chicago.* Written from a social learning perspective, this book addresses school consultation considerations helpful in classroom management of problem student behaviors. Initial chapters define the role of the consultant, outline negotiations with teachers and principals, and review relevant behavior concepts. Practical applications of behavioral principles follow using actual and potential consultation experiences, a point system, and basic problem-solving techniques. The final segment details data on current situations, personality variables, and affective components. *'79, 240 pp., $14.75*

CASE STUDIES IN CLINICAL AND SCHOOL PSYCHOLOGY *by* **Ralph F. Blanco** *and* **Joseph G. Rosenfeld,** *both of Temple Univ., Philadelphia, Pennsylvania.* The fifteen case studies presented encompass behavior and emotional problems, learning disabilities, sensory and multiple handicaps, and giftedness. The authors outline symptoms, etiology, treatments and follow-up. Workbook sections permit psychology trainees to sharpen diagnostic skills and create prescriptive interventions, and to score and interpret responses on a variety of psychological tests. The authors' treatments are listed separately for comparison. These treatments include psychotherapy, IEP strategies, desensitization, extinction, and others. *'78, 256 pp., 4 il., $11.50*

LEISURE COUNSELING: An Aspect of Leisure Education *edited by* **Arlin Epperson,** *Univ. of Ottawa, Ottawa, Ontario, Canada; and* **Gerald Hitzhusen,** *Univ. of Missouri, Columbia. (31 Contributors)* Leisure counseling, as one specific aspect of the overall leisure education process, is the focal point of this volume. While institutional or rehabilitation leisure counseling has dominated the field in the past, the authors see future counseling expanding into community settings and a wider range of client groups. The contributors identify needs, examine priorities, and draft implications for education and research. *'77, 392 pp., 16 il., 22 tables, $20.75*

THE COUNSELOR AND SUICIDAL CRISIS: Diagnosis and Intervention *by* **John L. Hipple** *and* **Peter Cimbolic,** *both of North Texas State Univ., Denton.* The discussions in this book will help the professional counselor provide quality treatment for the actively suicidal client and his or her family. Chapters offer detailed information on determining the depth of depression, estimating lethality, providing protection during crisis, assisting in identification and resolution of conflicts, and terminating treatment appropriately. Also presented are ideas on use of the telephone as an adjunct to face-to-face counseling. *'79, 128 pp., $9.75*

THE THEORY AND TECHNIQUE OF FAMILY THERAPY *by* **Charles P. Barnard,** *Univ. of Wisconsin, Menomonie, and* **Ramon Garrido Corrales,** *Counseling Center for Human Development, Kansas City, Missouri.* A well-balanced blend of both therapy and practical application, this book provides a comprehensive overview of the theoretical constructs in the field of family therapy. The reader will find a tremendous variety of sources and orientations, topics ranging from the roots of human motivation and family development to specific intervention techniques and didactic aids. Techniques for intervention in a variety of circumstances are examined, including such subjects as premarital counseling, divorce counseling, alcoholism, and death and the family. *'79, 336 pp., 13 il., 1 table, $14.75*



PEOPLE IN PAIN: A Guide to Pastoral Care *by* **James A. Vanderpool,** *District of Columbia Government Rehabilitation Center for Alcoholics, Occoquan, Virginia.* General counseling considerations are presented first in this concise volume followed by brief descriptions of atypical behavior. The case study method is then used to illustrate techniques for counseling individuals suffering from atypical and bizarre thinking, severe atypical feelings and emotional behavior, neuroses, depressions, atypical acting-out and antisocial behavior, alcoholism, sociopathology, drug addiction, and human sexuality problems. *'79, 208 pp., $12.75*

JUVENILE OFFENDERS (Rev. 6th Ptg.) *by* **Clyde B. Vedder,** *Univ. of Texas of the Permian Basin, Odessa. Foreword by* **Donal E. J. MacNamara.** For this Revised Sixth Printing, the author has updated and augmented the text and brought it into line with current practices. He continues to portray juvenile crime as it occurs in society, to note the various patterns of delinquency among juveniles, and to list official and informal treatment approaches. Specific chapter topics include the extent of juvenile delinquency, economic conditions and familial factors, community institutions, personality and behavior problems, apprehension and detention, and juvenile courts. *'79, 288 pp., 1 il., 5 tables, $11.95*

CAREER DEVELOPMENT AND COUNSELING OF WOMEN *edited by* **L. Sunny Hansen,** *Univ. of Minnesota, Minneapolis, and* **Rita S. Rapoza,** *Wilson Learning Corp., Eden Prairie, Minnesota. (46 Contributors)* The collection of articles in this text offers detailed discussion on the influences, both psychological and environmental, that either inhibit or facilitate the female decision-making and developmental process. Specific topics include occupational socialization, negotiating and planning for multiple roles, assessment of women's career interests, and cross-cultural perspectives of female career development. An extensive bibliography is included. *'78, 672 pp., 57 tables, $27.25*

breaking
through

In marked agitation with depression symptomatic relief may make the patient more accessible and responsive.

Rapid relief of marked agitation in many patients
The tranquilizer component alleviates symptoms of agitation and anxiety within a few days, without apparent dulling of mental acuity. Hypnotic effects from the tranquilizer component appear to be minimal, particularly in patients permitted to remain active. However, TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks.

Highly effective antidepressant action
The antidepressant component relieves symptoms of depression such as poor concentration and feelings of hopelessness as well as early morning awakening; adequate relief of symptoms may take a few weeks or even longer.

Helps break barriers to psychotherapy
As symptoms are relieved, many patients often communicate more effectively, become more cooperative, and are able to return to normal daily activities.

More prescribing convenience
There are now *five* tablet strengths of TRIAVIL for ease of dosage adjustment. For many patients with agitation and depression, you can now initiate therapy with one TRIAVIL™ 4-50, containing 4 mg perphenazine and 50 mg amitriptyline HCl, b.i.d. The regimen is simple, economical, and may well enhance patient compliance.

Treatment with TRIAVIL—a balanced view:
TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to overdosage of other drugs or mask other disorders. The possibility of suicide in depressed patients remains until significant remission occurs. Such patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

For marked agitation with depression

dual-action®

Triavil

containing perphenazine and amitriptyline HCl

MSD
MERCK SHARP & DOHME

Copyright © 1979 by Merck & Co., Inc.

Please see following page for a brief summary of prescribing information.

More dosage strengths
than any other formulation containing
a tranquilizer and an antidepressant

dual-action TRIAVIL®

containing perphenazine and amitriptyline HCl

Available:
TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-50: Each tablet contains
4 mg perphenazine and 50 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl.

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides. There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to perphenazine and other antipsychotic drugs is not known.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.
Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) have been reported and can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw. Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. Fine vermicular movements of the tongue may be an early sign of the syndrome. The full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; other adverse reactions reported with various phenothiazine compounds, but not with perphenazine, include grand mal convulsions, cerebral edema, polyphagia, pigmentary retinopathy, photophobia, skin pigmentation, and failure of ejaculation.

The phenothiazine compounds have produced blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia) and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur after long-term administration of some phenothiazines. Although it has not been reported in patients receiving TRIAVIL, the possibility that it might occur should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia have also been reported.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs and must be considered when amitriptyline is administered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesia of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; increased intraocular pressure; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness, weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

MSD
MERCK SHARP DOHME

Depression: Unhappily often a family affair...

“Please don’t cry.”

His mother's depressed. Her sleepless nights are filled with anxieties. She's become irritable and "unloving." He doesn't understand why she has changed.

In their study comparing imipramine pamoate with amitriptyline in depressed patients, Goldberg and Finnerty* found that the overall results indicated both drugs were equally effective in treating neurotic depression, with patients receiving Tofranil-PM tending to have a better quality of sleep. The difference was not statistically significant.

Before prescribing Tofranil-PM, please review a summary of the full prescribing information on following page.

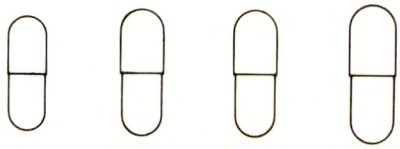
Tofranil-PM®
imipramine pamoate

Unsurpassed among tricyclics in treating symptoms of anxious depression

*Goldberg H L, Finnerty R J : Which tricyclic for depressed outpatients, imipramine pamoate or amitriptyline? Dis Nerv Syst *38*: 785-789 (Oct.) 1977.

Geigy

Tofranil-PM®
imipramine **pamoate**



Unsurpassed among tricyclics in treating a broad range of depressions—from the more retarded to the more anxious.

Effectively relieves sleep disturbances, anxiety, and other symptoms of depression.

Notable mood-brightening effect especially helpful in the more retarded depressions.

Good results can be seen with a starting dose of 75 mg h.s.; however, higher doses may be needed.

Capsules of*

75 mg | 100 mg | 125 mg | 150 mg

As with all tricyclics, sedation may occur. For details, please read the full prescribing information, a summary of which appears on this page.

*Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg of imipramine hydrochloride.

Geigy

Tofranil-PM®
imipramine pamoate

Indications For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states. One to three weeks of treatment may be needed before optimal therapeutic effects are evident.

Contraindications The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed.

The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings Extreme caution should be used when this drug is given to:

patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, congestive heart failure, myocardial infarction, strokes and tachycardia. These patients require cardiac surveillance at all dosage levels of the drug;

patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;

hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;

patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;

patients receiving guanethidine, clonidine, or similar agents, since imipramine pamoate may block the pharmacologic effects of these drugs;

patients receiving methylphenidate hydrochloride. Since methylphenidate hydrochloride may inhibit the metabolism of imipramine pamoate, downward dosage adjustment of imipramine pamoate may be required when given concomitantly with methylphenidate hydrochloride.

Since imipramine pamoate may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as operating an automobile or machinery, the patient should be cautioned accordingly.

Tofranil-PM may enhance the CNS depressant effects of alcohol. Therefore, it should be borne in mind that the dangers inherent in a suicide attempt or accidental overdosage with the drug may be increased for the patient who uses excessive amounts of alcohol. (See **Precautions**.)

Usage in Children: Tofranil-PM should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg, 100 mg, 125 mg and 150 mg). Each capsule contains imipramine pamoate equivalent to 75 mg, 100 mg, 125 mg or 150 mg imipramine hydrochloride.

Precautions An ECG recording should be taken prior to the initiation of larger-than-usual doses of imipramine pamoate and at appropriate intervals thereafter until steady state is achieved. (Patients with any evidence of cardiovascular disease require cardiac surveillance at all dosage levels of the drug. See **Warnings**.) Elderly patients and patients with cardiac disease or a prior history of cardiac disease are at special risk of developing the cardiac abnormalities associated with the use of imipramine pamoate. It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with imipramine pamoate and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, imipramine pamoate may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes.

An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine.

Concurrent administration of imipramine pamoate with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Usage During Pregnancy and Lactation:

Animal reproduction studies have yielded inconclusive results. (See also **Animal Pharmacology & Toxicology**.)

There have been no well-controlled studies conducted with pregnant women to determine the effect of imipramine on the fetus. However, there have been clinical reports of congenital malformations associated with the use of the drug. Although a causal relationship between these effects and the drug could not be established, the possibility of fetal risk from the maternal ingestion of imipramine cannot be excluded. Therefore, imipramine should be used in women who are or might become pregnant only if the clinical condition clearly justifies potential risk to the fetus.

Limited data suggest that imipramine is likely to be excreted in human breast milk. As a general rule, a woman taking a drug should not nurse since the possibility exists that the drug may be excreted in breast milk and be harmful to the child.

Patients should be warned that imipramine pamoate may enhance the CNS depressant effects of alcohol. (See **Warnings**.)

Imipramine pamoate should be used with caution in p
with significantly impaired renal or hepatic function.

Patients who develop a fever and a sore throat during
therapy with imipramine pamoate should have leukoc
differential blood counts performed. Imipramine pamo
should be discontinued if there is evidence of patholo
neutrophil depression.

Prior to elective surgery, imipramine pamoate should b
continued for as long as the clinical situation will allow

In occasional susceptible patients or in those receivin
ticholinergic drugs (including anti-parkinsonism agent
addition, the atropine-like effects may become more p
nounced (e.g., paralytic ileus). Close supervision and
adjustment of dosage is required when imipramine pa
is administered concomitantly with anticholinergic dru

Avoid the use of preparations, such as decongestants
local anesthetics, which contain any sympathomimetic
amine (e.g., epinephrine, norepinephrine), since it has
reported that tricyclic antidepressants can potentiate t
fects of catecholamines.

Caution should be exercised when imipramine pamoa
used with agents that lower blood pressure.

Imipramine pamoate may potentiate the effects of CN
pressant drugs.

Patients taking imipramine pamoate should avoid exc
exposure to sunlight since there have been reports of
sensitization.

Both elevation and lowering of blood sugar levels have
reported with imipramine pamoate use.

Adverse Reactions Note: Although the listing which f
includes a few adverse reactions which have not been
ported with this specific drug, the pharmacological
similarities among the tricyclic antidepressant drugs re
that each of the reactions be considered when imipran
administered.

Cardiovascular: Orthostatic hypotension, hypertensio
tachycardia, palpitation, myocardial infarction, arrhyth
heart block, ECG changes, precipitation of congestive
failure, stroke.

Psychiatric: Confusional states (especially in the elder
with hallucinations, disorientation, delusions; anxiety, r
lessness, agitation; insomnia and nightmares; hypoma
exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesias of ex-
tremities; incoordination, ataxia, tremors; peripheral
neuropathy; extrapyramidal symptoms; seizures, alter
in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associated sut
gual adenitis; blurred vision, disturbances of accommo
tion, mydriasis; constipation, paralytic ileus; urinary ret
tion, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photos
sitization; edema (general or of face and tongue); drug
cross-sensitivity with desipramine.

Hematologic: Bone marrow depression including agra
cytosis; eosinophilia; purpura; thrombocytopenia.

Gastrointestinal: Nausea and vomiting, anorexia, epig
distress, diarrhea; peculiar taste, stomatitis, abdominal
cramps, black tongue.

Endocrine: Gynecomastia in the male; breast enlarger
and galactorrhea in the female; increased or decrease
libido, impotence; testicular swelling; elevation or depr
of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver f
tion; weight gain or loss; perspiration; flushing; urinary
quency; drowsiness, dizziness, weakness and fatigue;
headache; parotid swelling; alopecia; proneness to fall

Withdrawal Symptoms: Though not indicative of addict
abrupt cessation of treatment after prolonged therapy r
produce nausea, headache and malaise.

How Supplied Tofranil-PM is available as follows:

75-mg, coral-colored capsules equivalent to 75 mg imi
ramine hydrochloride in bottles of 30, 100 and 1,000 ca
sules, and unit strip packages of 100.

100-mg, dark yellow/coral-colored capsules equivalent
mg imipramine hydrochloride in bottles of 30, 100 and 1
capsules.

INSOMNIA OFTEN DOES NO
BUT IT ALMOST ALWAYS STAND

A focus on this somatic complaint may hinder exploration into underlying psychopathology[1]

Patients with insomnia often find it difficult to express and/or control their aggressive feelings. Sleep is seen as a loss of control and remaining awake helps alleviate this fear. Such patients frequently tend to focus on their insomnia, rejecting or denying the possibility of existing psychopathology.

Psychotherapy, therefore, may be made more productive by the addition of a sleep medication for the insomnia.

For relief of insomnia, sleep laboratory studies have proven Dalmane® (flurazepam HCl/Roche) effective for just one night and effective through at least 28 consecutive nights of administration.[2]

Results of six separate sleep laboratory studies have shown that Dalmane was significantly effective in improving sleep induction and maintenance during short, intermediate and longer-term use.[2] Although the prolonged administration of Dalmane is seldom necessary, prolonged use should be accompanied by the appropriate patient evaluations, such as periodic blood counts and liver and kidney function tests.

A double-blind study has proven Dalmane® (flurazepam HCl/Roche) effective for psychiatric patients with insomnia[3]

Forty-nine hospitalized male patients received either Dalmane or placebo. Compared to placebo, Dalmane reduced the time needed to fall asleep, reduced the number of awakenings and increased total sleep time.[3]

TAND ALONE,
OUT.

WHEN YOU DECIDE A SLEEP MEDICATION IS INDICATED

ROCHE

DALMANE® (IV)
flurazepam HCl/Roche

One 30-mg capsule *h.s.*—usual adult dosage
(15 mg may suffice in some patients).
One 15-mg capsule *h.s.*—recommended initial dosage
for elderly or debilitated patients.

A WIDER MARGIN OF SAFETY[4]

Dalmane offers a safety profile comparably higher than many other sleep medications. There have been no reports of physical or psychological dependence when taken at recommended dosages. In controlled studies involving 2115 patients, the majority of side effects reported were of the sedative-type generally expected with a sleep medication. As with all medications in its class, Dalmane should be administered with caution to patients who are addiction-prone. Patients should also be cautioned about possible combined effects with alcohol and other CNS depressants.

4. Data on file, Medical Department, Hoffmann-La Roche Inc., Nutley NJ

Before prescribing Dalmane (flurazepam HCl/Roche), please consult complete product information, a summary of which follows:

Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Objective sleep laboratory data have shown effectiveness for at least 28 consecutive nights of administration. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.

Contraindications: Known hypersensitivity to flurazepam HCl.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).

***Usage in Pregnancy:* Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane (flurazepam HCl/Roche), a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.

Precautions: In elderly and debilitated patients, it is recommended that the dosage be limited to 15 mg to reduce risk of oversedation, dizziness, confusion and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies, or with impaired renal or hepatic function. Periodic blood counts and liver and kidney function tests are advised during repeated therapy.

Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.

Dosage: Individualize for maximum beneficial effect.
Adults: 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg **recommended** initially until response is determined.

Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

POLYDRUG ABUSE:

THE RESULTS OF A NATIONAL COLLABORATIVE STUDY

Edited by DONALD R. WESSON, KENNETH ADAMS, ALBERT S. CARLIN and GEORGE BESCHNER.

In 1973 the Special Action Office of Drug Abuse Prevention initiated a national study of polydrug abuse—the first attempt to reach, treat, and study a large sample of polydrug abusers. The methods and procedures used in this study were unique, encompassing thirteen different programs scattered across the country in a collaborative effort. Summarizing the results of this study, *Polydrug Abuse* describes demographic, psychological, and biomedical characteristics of individuals in treatment as well as a sample of users who were not in treatment. The book examines the innovative outreach and case-finding techniques that brought people with polydrug problems into clinical settings for systematic evaluation. Timely and important reading for professionals in medicine, psychology, and the drug abuse field, the book helps us to better understand the polydrug problem so that we can be in a better position to develop intervention strategies.

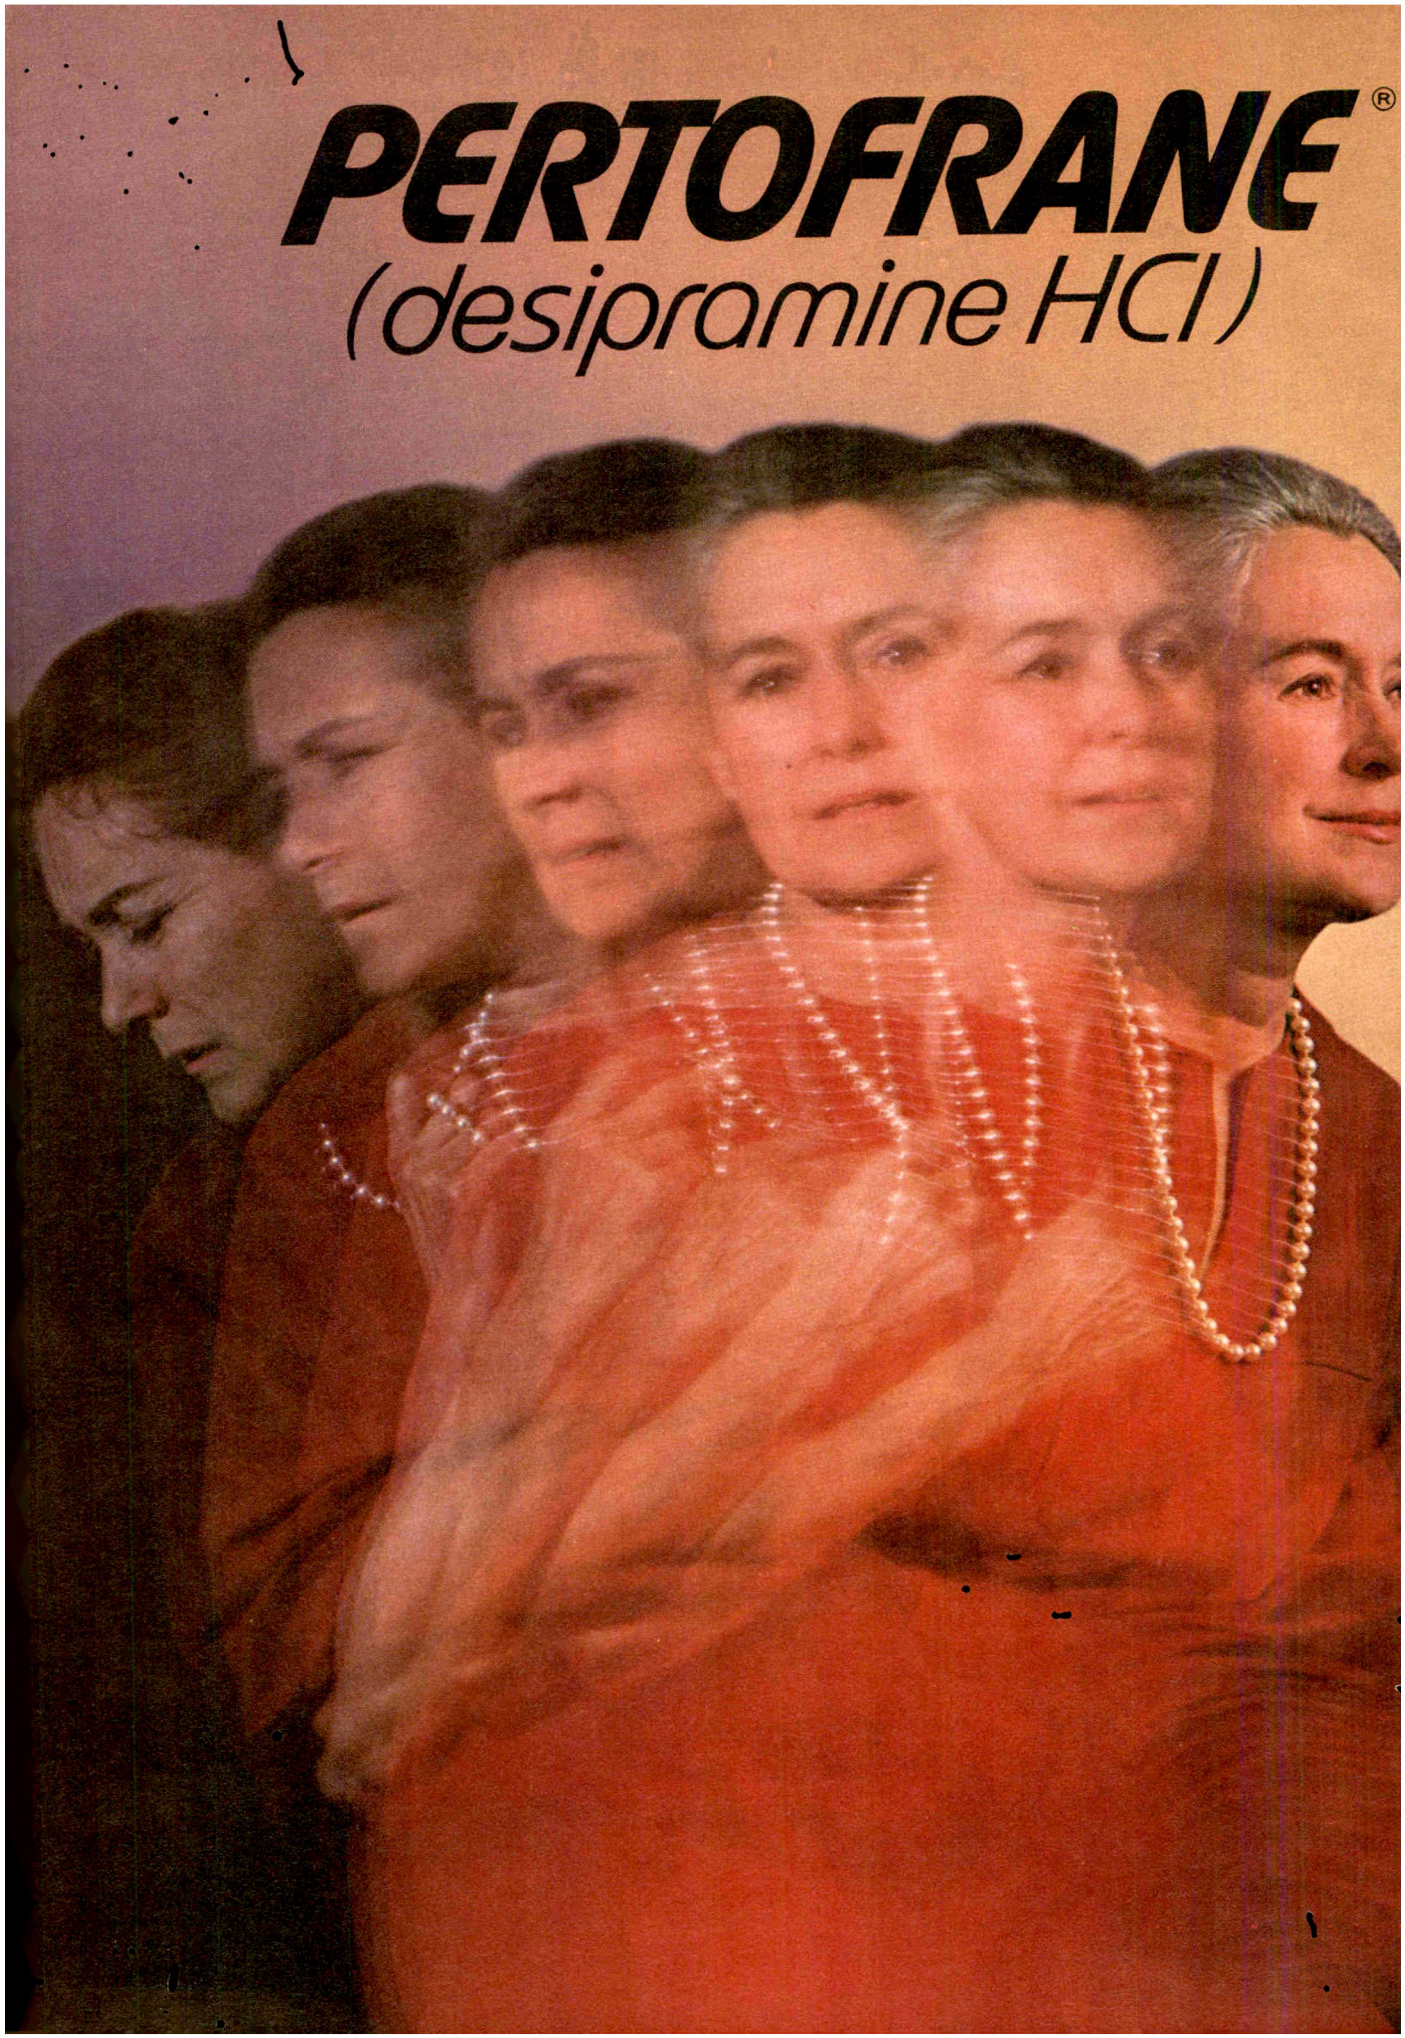
The Brown Schools: Specialists in Residential Treatment

Residential treatment has become highly specialized in the field of mental health. It is a specific treatment modality for those who need a totally planned and structured environment.

The Brown Schools has developed a wide range of professional services that can be utilized to implement an individually planned residential treatment program. The degree of structure and protection, the intensity of therapy, the methods of education and training are controlled and modified with the resident's changing needs.

Professionals in the areas of psychiatry, psychology, nursing, social work, education, prevocational training, speech pathology, and recreation have developed expertise in the specific area of residential treatment. Each service area is designed as a component of an integrated therapeutic milieu.



The three residential treatment centers of The Brown Schools provide complete programming for those in need of twenty-four hour care. Services are available for children, adolescents, and adults with emotional disturbance, mental retardation, and neurological impairment. Two small group homes in Austin provide for reintegration into the community and complement the services offered in the other centers. For information, write:

PERTOFRANE®
(desipramine HCl)

the antidepressant to turn to...

when the first tricyclic fails

"As amitriptyline and desipramine represent the extremes of the differences among the tricyclics, many clinicians start treatment with one or the other and then follow with the alternative drug if response to the first was unsatisfactory."[1]

when side effects are a problem

"Desipramine might be more appropriate for patients who are sensitive to anticholinergic effects or in whom sedative action is not desirable."[2]

when activity is important

"Desipramine seems ideally suited to use in an active ambulatory patient population..."[3]

Psychiatry 135:722, 1978. 3. Barnes, R. J.: Clinical depression: Double-blind study of desipramine and amitriptyline in depressive neurosis, Scientific Exhibit, Southern Medical Convention, Miami, Fla., Nov. 16-19, 1975.

PERTOFRANE® (desipramine HCl)

when the first tricyclic fails

Indication: For relief of mental depression. **Contraindications:** Do not use MAO inhibitors concomitantly or within 2 weeks of the use of this drug. Hyperpyretic crises or severe convulsive seizures may occur with such combinations; potentiation of adverse reactions can be serious or even fatal. When substituting Pertofrane (desipramine HCl) in patients receiving an MAO inhibitor, allow an interval of at least 14 days. Initial dosage in such patients should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated following recent myocardial infarction and in patients with a known hypersensitivity to tricyclic antidepressants. **Warnings:** Activation of psychosis may occasionally be observed in schizophrenic patients. Due to atropine-like effects and sympathomimetic potentiation, use only with the greatest care in patients with narrow-angle glaucoma or urethral or ureteral spasm. Do not use in patients with the following conditions unless the need outweighs the risk: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (may lower seizure threshold). This drug may block the action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents. Hypertensive episodes have been observed during surgery. The concurrent use of other central nervous system drugs or alcohol may potentiate adverse effects. Since many such drugs may be used during surgery, desipramine should be discontinued prior to elective procedures. The potentiation resulting from excessive use of alcohol may increase the danger inherent in a suicide attempt or overdosage. Caution patients on the possibility of impaired ability to operate a motor vehicle or dangerous machinery. Do not use in women who are or may become pregnant, or in children under 12 years of age, unless the clinical situation warrants the potential risk. Because of increased sensitivity to the drug, use lower than normal dosage in adolescent and geriatric patients. **Precautions:** Potentially suicidal patients require careful supervision and protective measures during therapy. Prescriptions should be limited to small quantities. Discontinuation of the drug may be necessary in the presence of increased agitation and anxiety shifting to hypomanic or manic excitement. Atropine-like effects may be more pronounced (e.g. paralytic ileus) in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents). Prescribe cautiously in hyperthyroid patients and in those receiving thyroid medications; transient cardiac arrhythmias have occurred in rare instances. Periodic blood and liver studies should supplement careful clinical observations in all patients undergoing extended courses of therapy. **Adverse Reactions:** The following have been reported: *Nervous System:* dizziness, drowsiness, insomnia, headache, disturbed visual accommodation, tremor, unsteadiness, tinnitus, paresthesias, changes in EEG patterns, epileptiform seizures, mild extrapyramidal activity, falling and neuromuscular incoordination. A confusional state (with such symptoms as hallucinations and disorientation), particularly in older patients and at higher dosage, may require discontinuation of the drug. *Gastrointestinal Tract:* anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea. *Skin:* skin rashes (including photosensitization), perspiration and flushing sensations. *Liver:* rare cases of transient jaundice (apparently of an obstructive nature) and liver damage. If jaundice or abnormalities in liver function tests occur, discontinue the drug and investigate. *Blood Elements:* bone-marrow depression, agranulocytosis, thrombocytopenia and purpura. If these occur, discontinue the drug. Transient eosinophilia has been observed. *Cardiovascular System:* orthostatic hypotension and tachycardia. Carefully supervise patients requiring concomitant vasodilating therapy, particularly during initial phases. *Genitourinary System:* urinary frequency or retention and impotence. *Endocrine System:* occasional hormonal effects, including gynecomastia, galactorrhea and breast enlargement, and decreased libido and estrogenic effect. *Sensitivity:* urticaria and rare instances of drug fever and cross-sensitivity with imipramine. **Dosage:** All patients except geriatric and adolescent: 75 to 150 mg./day in divided doses or as single daily dose. Dosage may be increased up to 200 mg. daily. Geriatric and adolescent patients should usually be started with lower dosage (25 to 50 mg. daily) and may not tolerate higher doses. Dosage may be increased up to 100 mg. daily. Lower maintenance dosages should be continued for at least 2 months after obtaining a satisfactory response. Therapy may be given in divided doses or as a single daily dose. **How Supplied:** 25 mg. capsules (pink), bottles of 100 and 1000. Also, 50 mg. capsules (maroon and pink), bottles of 100 and 1000.

USV LABORATORIES

Manati, P.R. 00701

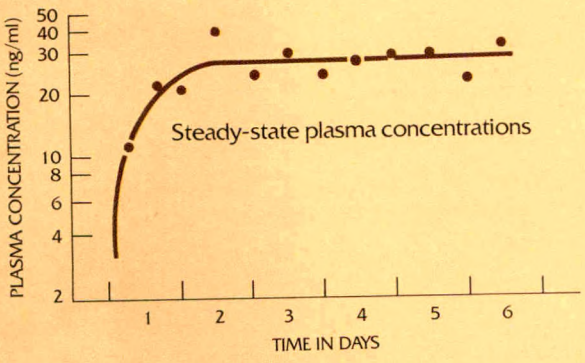
How to tell ATIVAN from other benzodiazepines.

Ativan is an effective, well-tolerated antianxiety agent. So are other benzodiazepines. But here are three ways Ativan stands out pharmacokinetically.*

1. Uncomplicated metabolic profile.

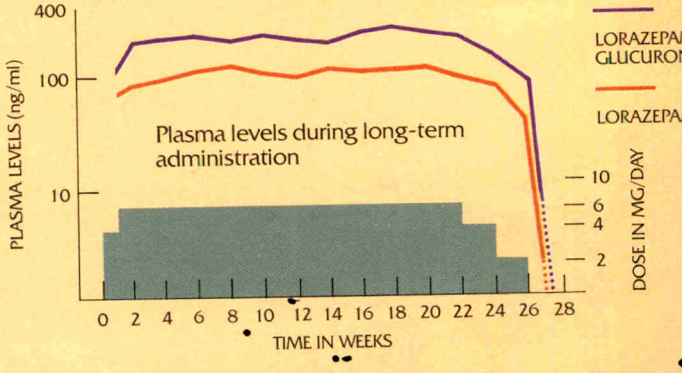
In contrast to most other benzodiazepines, the metabolic pathway of Ativan is straightforward. Ativan is active as given. Just one step from an active compound to an inactive one.

2. Steady-state levels achieved rapidly.



Most benzodiazepines take at least 7 to 10 days to reach steady-state serum levels. With Ativan, that equilibrium is reached in 2 to 3 days. A factor that can be important when you modify dosage schedules to meet individual needs.

3. No accumulation o multiple metabolites.

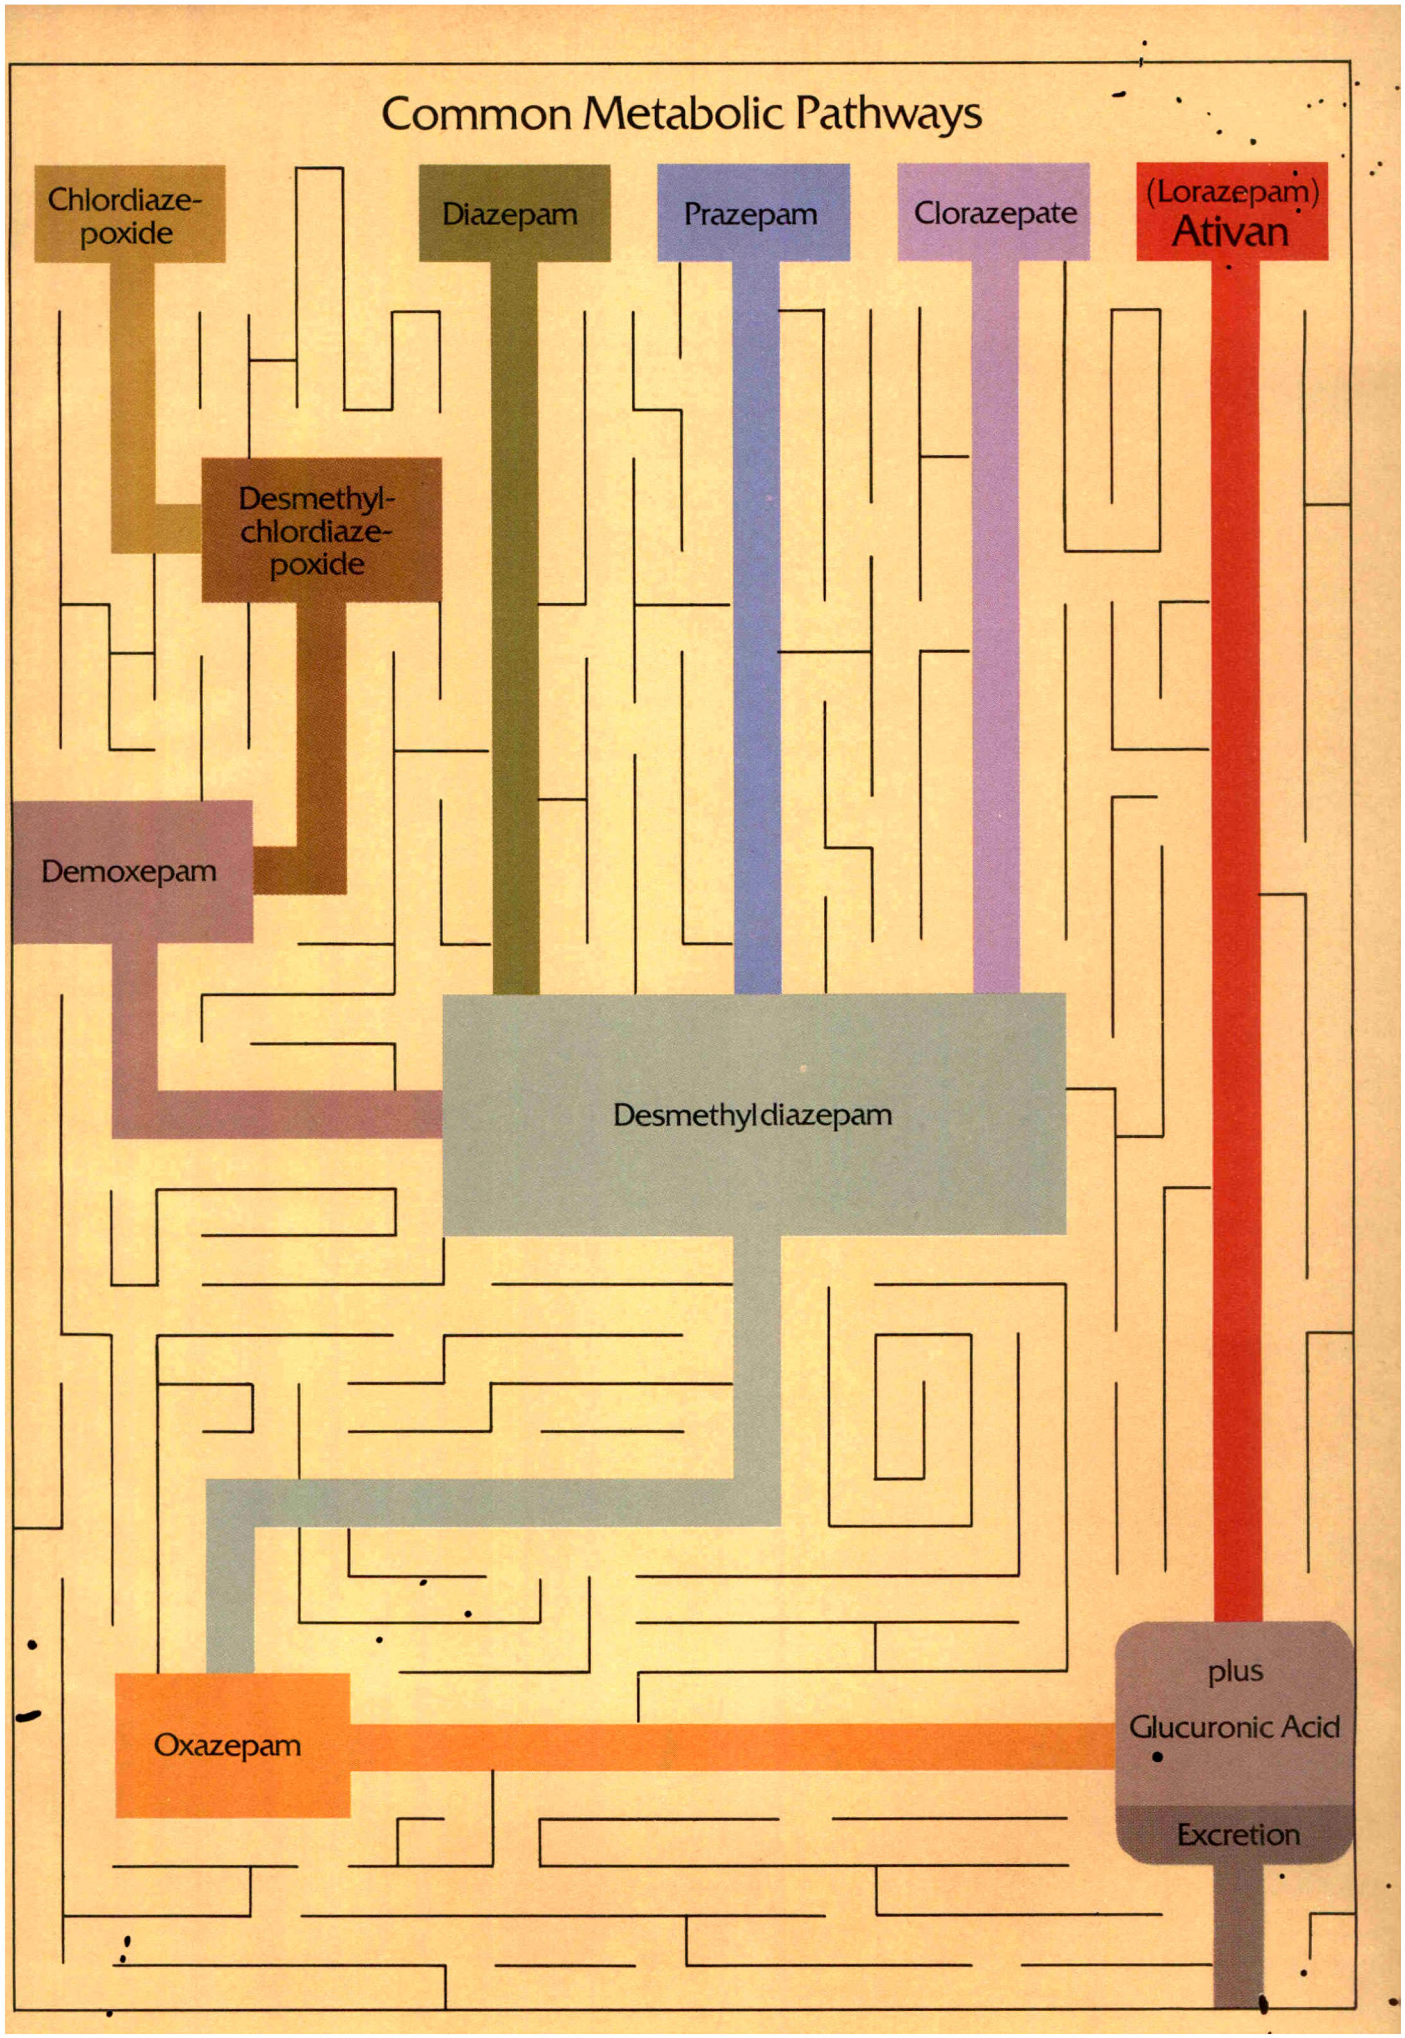


Because Ativan has no active metabolites to be eliminated at varying rates, steady-state levels are achieved predictab and smoothly. Six-month studies show no evidence of drug-accumulation above steady-state levels even at maximum daily dosages.

*The pharmacokinetic profile of a drug cannot, at present, be directly related to its therapeutic effectiveness.

Please refer to page after next for a summary of prescribing information.

Concentrations of lorazepam on repeated-dose regimen (single 1-mg. tablets given at 9 a.m., 3 p.m. and 9 p.m. daily for 6 days). A steady state is achieved after the second day, and is maintained thereafter.



Lorazepam and lorazepam glucuronide plasma levels in ng/ml during chronic oral administration of the drug over a period of six months. Each point represents the mean of 8 subjects. The daily maintenance dose in milligrams per subject is given at weekly intervals.

prescribing information

Contraindications: Ativan is contraindicated in patients with known sensitivity to the benzodiazepines or with acute narrow-angle glaucoma.

Warnings: Ativan is not recommended for use in patients with a primary depressive disorder or psychosis. As with all patients on CNS-acting drugs, patients receiving lorazepam should be warned not to operate dangerous machinery or motor vehicles and that their tolerance for alcohol and other CNS depressants will be diminished.

Physical and Psychological Dependence: Withdrawal symptoms similar in character to those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepine drugs. These symptoms include convulsions, tremor, abdominal and muscle cramps, vomiting and sweating. Addiction-prone individuals, such as drug addicts and alcoholics, should be under careful surveillance when receiving benzodiazepines because of the predisposition of such patients to habituation and dependence.

Precautions: In patients with depression accompanying anxiety, a possibility for suicide should be borne in mind.

For elderly or debilitated patients, the initial daily dosage should not exceed 2 mg in order to avoid oversedation.

Ativan dosage should be terminated gradually since abrupt withdrawal of any antianxiety agent may result in symptoms similar to those for which patients are being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

The usual precautions for treating patients with impaired renal or hepatic function should be observed.

In patients where gastrointestinal or cardiovascular disorders coexist with anxiety, it should be noted that lorazepam has not been shown to be of significant benefit in treating the gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than one year at 6 mg/kg/day. The no-effect dose was 1.25 mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10 mg per day). The effect was reversible only when the treatment was withdrawn within two months of first observation of the phenomenon. The clinical significance of this is unknown. However, use of lorazepam for prolonged periods and in geriatric patients requires caution, and there should be frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness of Ativan in children of less than 12 years have not been established.

Essential Laboratory Tests: Some patients on Ativan have developed leukopenia and some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended for patients on long-term therapy.

Clinically Significant Drug Interactions: The benzodiazepines including Ativan produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

Carcinogenesis and Mutagenesis: No evidence of carcinogenic potential emerged in rats during an 18-month study with Ativan. No studies regarding mutagenesis have been performed.

Pregnancy: Reproductive studies in animals were performed in mice, rats, and two strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all of these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At doses of 40 mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses.

The clinical significance of the above findings is not known. However, an increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during the first trimester of pregnancy has been suggested in several studies. Because the use of these drugs is rarely a matter of urgency, the use of lorazepam during this period should almost always be avoided. The possibility that a woman of child-bearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant, they should communicate with their physician about the desirability of discontinuing the drug.

In humans, blood levels obtained from umbilical cord blood indicate placental transfer of lorazepam and lorazepam glucuronide.

Nursing Mothers: It is not known whether oral lorazepam is excreted in human milk like the other benzodiazepine tranquilizers. As a general rule, nursing should not be undertaken while a patient is on a drug since many drugs are excreted in human milk.

Adverse Reactions: Adverse reactions, if they occur, are usually observed at the beginning of therapy and generally disappear on continued medication or upon decreasing the dose. In a sample of about 3,500 anxious patients, the most frequent adverse reaction to Ativan is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent adverse reactions are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, together with various gastrointestinal symptoms and autonomic manifestations. The incidence of sedation and unsteadiness increased with age.

Small decreases in blood pressure have been noted but are not clinically significant, probably being related to the relief of anxiety produced by Ativan.

Overdosage: In the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

Manifestations of Ativan overdosage include somnolence, confusion and coma. Induced vomiting and/or gastric lavage should be undertaken followed by general supportive care, monitoring of vital signs and close observation of the patient. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection, U.S.P. Caffeine and Sodium Benzoate Injection, U.S.P. may be used to counteract CNS depressant effects. The usefulness of dialysis has not been determined.

Dosage and Administration: Ativan is administered orally. For optimal results, dose, frequency of administration and duration of therapy should be individualized according to patient response. To facilitate this, scored 1.0 and 2.0 mg tablets are available.

The usual range is 2 to 6 mg/day given in divided doses, the largest dose being taken before bedtime, but the daily dosage may vary from 1 to 10 mg/day. For anxiety, most patients require an initial dose of 2 to 3 mg/day given b.i.d. or t.i.d.

For insomnia due to anxiety or transient situational stress, a single daily dose of 2 to 4 mg may be given, usually at bedtime.

For elderly or debilitated patients, an initial dosage of 1 to 2 mg/day in divided doses is recommended, to be adjusted as needed and tolerated.

The dosage of Ativan should be increased gradually when needed to help avoid adverse effects. When higher dosage is indicated, the evening dose should be increased before the daytime doses.

How Supplied: Ativan (lorazepam) is available in scored 1.0 and 2.0 mg tablets in bottles of 100.

This 277-page Report of the Conference, sponsored by APA and President Carter's Commission on Mental Health, identifies the chronic mental patient population, spells out where they are and what their needs and rights are. It specifies what programs work and what programs do not work in meeting the needs of these patients. It elaborates on the obstacles to implementing effective programs and the economic issues involved. It delineates the pros and cons of case management and specifies responsibility for coordinating, implementing, and monitoring services to chronic mental patients.

Finally, it proposes a *Call to Action* which opens with this statement: "There is no more urgent concern than the needs of the chronic mentally ill who suffer from severe, persistent, or recurrent mental illnesses with residual social and vocational disabilities. As a result of the deinstitutionalization programs of the past decade and the continuing growth of high risk populations that generate chronically ill, the problems associated with the care of these patients constitute a national crisis."

Since the Conference, the APA Assembly and the Board of Trustees have both approved the "Call to Action" which calls upon the APA to take the lead in undertaking programs to elevate the prestige and value of work with chronic mentally ill patients.

It follows that all APA members should be thoroughly versed in the current problems of this chronic patient population. This is best accomplished by reading this Conference Report now available from APA Publications Services at $11.00 a copy.

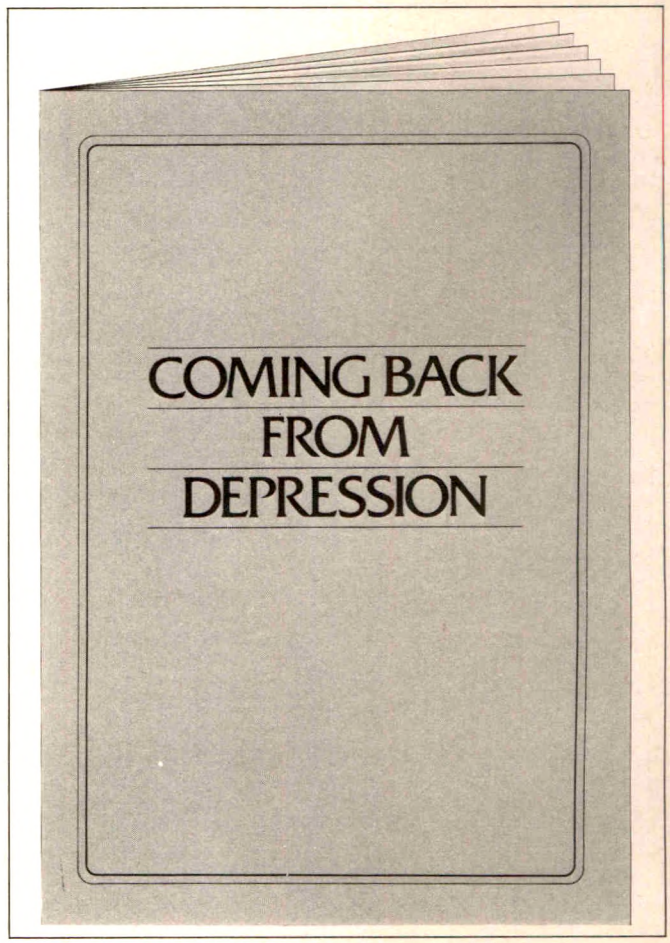
You know what to expect from antidepressant therapy;



...but does your patient?

You know that it generally takes two or three weeks for tricyclic therapy to begin working in depression...and that some side effects may be encountered. But, in all likelihood, your patient doesn't.

To lessen the time you spend in explanation and to increase patient compliance, we've prepared a special patient information booklet in conjunction with the introduction of Amitid—a high quality, low cost amitriptyline from Squibb. Entitled "COMING BACK FROM DEPRESSION," this booklet offers encouragement to depressed patients, helps you explain the basic facts about depression and outlines some of the things to be expected during therapy, the good *and* the bad.

You can get a supply of this carefully written booklet simply by sending a request on your letterhead to E. R. Squibb & Sons, Inc., Department 31, P.O. Box 4000, Princeton, New Jersey 08540. And you can save your patients significant amounts of money by specifying Amitid on all your amitriptyline prescriptions.

Amitid is available in five separate strengths, and is bioequivalent to the leading brand of amitriptyline. Amitid offers all the known clinical advantages of amitriptyline—relieving a wide range of depression-associated symptoms. Yet Amitid is priced considerably lower than other leading brands;* bringing savings that should help ease the burden of depression for patients...just a little bit more!

*Based on manufacturers' published prices as of August 1, 1978.

Introducing

Amitid™

Amitriptyline Hydrochloride Tablets USP

lowers the cost, not the quality, of antidepressant therapy

Please see following page for brief summary.

SQUIBB®

Amitid™ (Amitriptyline Hydrochloride Tablets USP)

DESCRIPTION: Amitriptyline hydrochloride is a dibenzocycloheptadiene derivative available for oral administration as FILMLOK® tablets (FILMLOK is a Squibb trademark for veneer-coated tablets).

INDICATIONS: For relief of symptoms of depression alone or accompanied by anxiety. Endogenous depression is more likely to be alleviated than are other depressive states.

CONTRAINDICATIONS: Contraindicated in patients with a history of hypersensitivity to amitriptyline. Do not administer concomitantly with a monamine oxidase (MAO) inhibitor since hyperpyretic crises, severe convulsions, and deaths occurred when tricyclic antidepressants and MAO inhibitors were administered simultaneously. When an MAO inhibitor is to be replaced by amitriptyline, allow 14 days to elapse after discontinuation of the former and then initiate amitriptyline cautiously and gradually increase dosage until optimum response is achieved. Amitriptyline is not recommended for use during the acute recovery phase following myocardial infarction.

WARNINGS: Amitriptyline may block antihypertensive action of guanethidine or similarly acting drugs. Use with caution in patients with history of seizures and (because of atropine-like action of amitriptyline) in patients with history of narrow-angle glaucoma (even average doses may precipitate an attack), increased intraocular pressure, or urinary retention. Closely watch patients with cardiovascular disorders since, in addition to having caused myocardial infarction and stroke, tricyclic antidepressants (including amitriptyline) particularly with high dosage have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Close supervision is required when amitriptyline is given to hyperthyroid patients or those on thyroid medication. Amitriptyline may impair mental and/or physical abilities required for performance of hazardous tasks such as operating machinery or driving a motor vehicle. Bear in mind that in patients who may use alcohol excessively the potentiation may increase the danger inherent in any suicide attempt or overdosage.

Usage in Pregnancy: Safe use during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women who may become pregnant, weigh the possible benefits against the possible hazards to the mother and child. Animal reproduction studies have been inconclusive, and clinical experience has been limited.

Usage in Children: At the present time, not recommended for patients under 12 years of age because of lack of experience with use in children.

PRECAUTIONS: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances the dose of amitriptyline may be reduced or a major tranquilizer may be administered concurrently.

Closely supervise and carefully adjust dosage in concomitant use with anticholinergic or sympathomimetic drugs, including combination of epinephrine and local anesthetics. Paralytic ileus may occur with concomitant use of tricyclic antidepressants and anticholinergic-type drugs. Caution is advised if used concurrently with large doses of ethchlorvynol since transient delirium has been reported when one gram of that drug and 75 to 150 mg of amitriptyline HCl were administered. Amitriptyline may enhance response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs. Potentially suicidal patients should not have easy access to large quantities of the drug. Prescriptions should be written for the smallest amount feasible. Limit concurrent administration of this drug and electroshock therapy to patients for whom it is essential since the hazards associated with such therapy may be increased. Discontinue this drug, when possible, several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use amitriptyline with caution in presence of impaired liver function.

ADVERSE REACTIONS: NOTE: A few of the adverse reactions listed below have not been reported with this specific drug, but each of the reactions should be considered when administering amitriptyline because of pharmacological similarities among tricyclic antidepressants.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, and stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness; tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; and syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, and dilatation of the urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, and edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, and thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, and black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, and elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, and alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

For full prescribing information, consult package insert.

HOW SUPPLIED: Available for oral administration in tablets providing 10, 25, 50, 75, and 100 mg amitriptyline hydrochloride. The 10, 25, and 50 mg tablets are available in bottles of 100 and 1000. The 75 and 100 mg tablets are available in bottles of 100.

PLAN AHEAD!!! Order your 1980 Appointment Book Now !!!

The "week-at-a-glance" Appointment Book, published by the American Psychiatric Association, has been specifically developed to satisfy the needs of psychiatrists. It contains a comprehensive list of addresses and annual meeting dates of all major organizations and agencies of interest to psychiatrists. Members who have not tried this book in the past are urged to do so. It is returnable within 30 days for a full refund if not acceptable. (Returned copies must be received in saleable condition.)

The Pocket Size Appointment Book is also available and may be ordered in combination with the Desk Appointment Book.

Copies will be available July 1979

DESK: $12.00
POCKET: $6.00
BOTH: $15.00

a consideration beyond efficacy alone...

Infrequent akathisia and other disabling extrapyramidal effects...

The rapidly rising readmission rate among discharged psychotic patients is mainly due to noncompliance with antipsychotic drug therapy. And this, in turn, may be largely attributed to disabling extrapyramidal side effects, notably akathisia.[1]

Although extrapyramidal effects are characteristic of antipsychotic agents in general, with Mellaril (thioridazine) such effects are infrequent. Adding an antiparkinsonian agent—which can cause its own side effects—can usually be avoided. Mellaril (thioridazine) is contraindicated in patients with severe hypotensive or hypertensive heart disease.

Extrapyramidal Effects of Selected Antipsychotic Agents*[2]

DRUG	EXTRAPYRAMIDAL EFFECTS
acetophenazine	moderate
chlorpromazine	moderate
chlorprothixene	moderate
fluphenazine	high
haloperidol	high
perphenazine	high
prochlorperazine	high
thioridazine **(MELLARIL®)**	low
thiothixene	moderate
trifluoperazine	high

*Based on antipsychotic dosage ranges

Mellaril® (thioridazine)

TABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP

MELLARIL-S™ (thioridazine) SUSPENSION, per 5 ml: thioridazine base equivalent to 100 mg thioridazine HCl, USP

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

THE AMERICAN JOURNAL OF PSYCHIATRY

"Folk" Criteria for the Diagnosis of Mental Illness in Rural Laos: On Being Insane in Sane Places

BY JOSEPH WESTERMEYER, M.D., PH.D., AND RONALD WINTROB, M.D.

"Folk" criteria for identifying the mentally ill, as distinguished from folk theories about the causes of mental illness, have been comparatively neglected in cultural psychiatry. The authors describe the criteria by which villagers in Laos labeled 35 subjects as baa *(insane). Unprovoked assaultive or destructive behavior, social isolation, self-endangerment due to neglect of personal needs, nonviolent but socially disruptive or inappropriate behavior, and inability to do productive work were found to be important folk criteria. The authors emphasize that folk criteria for mental illness are determined primarily by the persistence of socially dysfunctional behavior rather than by disturbances in thought and affect.*

"FOLK" THEORIES regarding mental disorder have been studied in several societies (1-6). Relatives of psychotic patients have also been surveyed regarding their attitudes toward the mentally ill and their treatment (7-9). On the other hand, folk criteria for labeling a particular person as mentally ill have been comparatively neglected.

The study of the mentally ill in Laos provided an opportunity to determine such folk criteria *not* influenced by psychiatrists or other mental health professionals, since there were no such practitioners there. Diagnoses of mental illness were made by community members. The purpose of this study was to clarify the criteria used for arriving at this form of social labeling or "folk diagnosis."

Received May 10, 1978; accepted Aug. 23, 1978.

Dr. Westermeyer is Professor of Psychiatry, University of Minnesota, Minneapolis, Minn. Dr. Wintrob is Professor of Psychiatry and Anthropology, University of Connecticut Health Center, Farmington, Conn. Address reprint requests to Dr. Westermeyer, Department of Psychiatry, University Hospitals, Box 393, Mayo Memorial Building, Minneapolis, Minn. 55455.

This study was supported in part by the Minnesota Medical Foundation and the International Programs Office at the University of Minnesota.

Drs. Jerry Kroll, Lloyd Sines, and Vicente Tuason collaborated in assigning psychiatric diagnoses, Mr. Tou Fu Vang and Ms. Beth Stone assisted in tabulating and analyzing the data, and Mr. Phimpha assisted in collecting the data.

METHOD

We surveyed 27 villages in rural Laos in 1975 to identify persons socially labelled as *baa*, or insane. Characteristics of the 35 subjects so designated are summarized in table 1. Psychiatric diagnoses were assigned independently by a panel of 4 experienced clinicians to whom summaries of the clinical data on each case were provided. This procedure has been described elsewhere (10). For each *baa* subject, a mean of 6.9 informants were interviewed, consisting of family, neighbors, village elders, and Buddhist monks. They were asked on what basis they assigned the social label of *baa* to the individual; each answer was probed for further details. There were no health workers or individuals with more than 10 years of formal education among the informants. All informants were members of the Lao ethnic group.

Data were obtained from each *baa* person's informants in a group setting. Any given response or "criterion" was counted only once for each subject. That is, even though two informants might say that a given person was eating garbage, that item was counted only one time. Items related by the informants were grouped using the informants' frame of reference insofar as possible.

The least number of responses reported for a given *baa* subject was 5 and the most was 19, with a mean of 12.4 (standard deviation of 3.9) and a median of 12 items per subject. The 3 subjects with the lowest number of items (i.e., 5, 6, and 7) had fewer than the average number of informants, and these informants did

not know the *baa* individuals well. These 3 subjects were vagrants whose family members could not be located. In the case of the 3 subjects with the highest ratings (2 with 18 items and 1 with 19) the high ratings were not related to the number of informants. These 3 subjects had extremely high scores on several clinical rating scales for psychopathology; they were severely impaired socially, and their care constituted a tremendous burden for their family and extended kinship.

Data on folk diagnosis and the onset of unusual or problematic behavior were obtained from family members who shared the same household with the *baa* subject. In addition, these same data were obtained from relatives not sharing the same household, as well as from neighbors, merchants, and other people in the neighborhood or village. The reports given by these different groups were then compared. (Information from family members could not be obtained for 6 people who were no longer living in their home village or close to kinship members.)

FINDINGS

Categories of Criteria

These categories are presented in the approximate order that informants tended to follow in relating the items.

Danger to others and property. Unprovoked assaultive behavior was reported as a criterion in 19 cases. Fourteen *baa* subjects attacked others with their fists or feet, 2 used weapons such as a board or knife, and 3 used both methods. Two women severely beat their own children for no apparent reason, and a man struck his small grandchildren on several occasions.

Eight subjects had threatened others verbally; 3 of them had not actually harmed anyone.

Informants for 8 subjects specified destruction of property as a criterion for the *baa* label. Damage was extensive, as the following case example illustrates:

> A 24-year-old man suddenly became argumentative with his family. He began throwing furniture and household items around the house. During the next few days, he threw furniture out of doors and windows. Having emptied the house of the furniture, he began ripping up clothes and bedding. By the time he could be restrained, he had torn down one wall of the family's wood frame house.

In each of these 8 cases there were also reports of unprovoked violence toward others and/or self. Instances of violence toward property not reported as a criterion for being *baa* (but subsequently elicited by direct questions) tended to be rather minor (e.g., pounding the side of a house with a board but not creating major damage), compared with reported cases (e.g., burning a family member's clothes, destroying furniture, burning down a kitchen).

There was harm by neglect in the case of a woman who became *baa* shortly after the birth of a daughter. Since she fed and cared for the infant irregularly, the child did not gain weight and gradually became weak, thin, and ill. Family members tried to assume care of the child, but the mother vehemently refused to relinquish the care to others. The child died of malnutrition during the second year of life.

Only 1 person, a 22-year-old man who had been *baa* for 4 years, had assaulted animals; he killed a dog and a cat by strangling them. This man had also threatened to kill himself, had assaulted several people in the village, and had threatened to knife children who teased him.

Danger to self. While some reported behaviors were apparently not intended by the *baa* person to be dangerous, they nonetheless produced a risk of injury to 26 subjects. Examples of self-risk were as follows:

> Once he drank mosquito poison saying it was a medicine for his cough. Sometimes he goes down the street as though he were a car or a truck himself, ignoring the traffic.

> Recently she climbed an electrical pole and danced and sang up there near the wires like she was a monkey. [The wires were 220 volts and known to be dangerous.]

Informants reported "sleeping in the open" as a criterion for assigning a *baa* diagnosis to 8 subjects. This behavior was cause for marked social concern in Laos, since exposure with subsequent fever and death was known as a common cause of death among *baa* individuals.

There were 5 reports that the *baa* individual's behavior had led to self injury, albeit sometimes in an indeliberate way. For example, one man who believed that he was an "important general" was severely beaten by the military police after he had stolen a jeep and driven it until it ran out of gas.

There were 3 cases of eating garbage or other unsanitary material. All 3 of these *baa* subjects had expressed the idea that people were trying to poison them. Thus they did not beg for food (as vagrant *baa* people usually did) or accept food from family or neighbors. A typical case was as follows:

> Last week when a car struck and killed a cat, he tore it open and ate it. He drinks filthy water and eats out of garbage pails. Once he made a funeral pyre for a dead goat as though it were a human [the Buddhist Lao cremate their dead], and then he ate the goat.

One man attempted to kill himself by not eating. He had been acutely psychotic for 10 days when encountered during the course of this study and was severely dehydrated, comatose, and near death.

Running away did involve some risk to *baa* persons themselves, but none of the subjects in this study sustained serious injury in this manner. Moreover, reports of serious injuries or death resulting from running away were rare. Since this type of behavior appeared to be more a social problem than a risk to self, it is included in a subsequent section.

Nonviolent socially disruptive behavior. Violence toward self, others, and property produced problems for the family and community of these *baa* subjects. Other behaviors, nonviolent in themselves, also caused a variety of problems for family, community, and society.

The most common complaint in this category was that the *baa* subject refused or was unable to work; this occurred in 27 cases. (Later direct questioning revealed that 34 of the 35 subjects were unproductive or underproductive.) Since the per capita gross national income was $70[1] in U.S. currency this behavior had major implications for the family and community in terms of survival.

Informants complained of *baa* subjects "wandering or running away" in 19 cases. Some wandered along roadways, eventually stopping in villages where people would shelter them until their relatives could be contacted and come and get them. Other individuals wandered into the forest, where they were at risk from starvation and dangerous animals. Their absence caused considerable distress to their families, in part because violent death would create both a spiritual and a social "stain" on the family. (It is widely believed in rural Laos that people who die violently may return as malevolent spirits to torment the family.) Families and neighbors often expended considerable time and effort in retrieving them.

"Yelling or screaming at night" was a complaint in 7 cases. This was a socially disturbing behavior because most Lao homes are built in such a way that screaming or yelling can easily be heard throughout an entire village.

Four subjects—all young men—created social crises that led to their being jailed for illegal activities. One 28-year-old *baa* man went to the homes of high government officials and declared that he was waiting to be paid. He was jailed for 15 days on suspicion that he was a spy. In another case, a 20-year-old man was a paratrooper when he first became *baa*. He behaved as though he were a high-ranking officer. He was placed in the military jail because he refused to obey orders and pretended that he was an officer.

Problems in speech and communication. There were 26 reports regarding incomprehensible or nonsensical speech. These involved speech that was not intelligible to the informants (16 cases), talking or singing to oneself while ignoring others (7 cases), and incessant talking (3 cases). One informant described a *baa* subject as follows:

> He talks to himself all the time and laughs to himself. If you ask why he is laughing, he says, "I wasn't laughing."

Angry yelling and cursing (*daa*) were reported in 18 cases. The form of some curses was appreciably different from and taken more seriously than in the United States in that they were curses invoking spirit possession or soul loss. Cursing in these cases was usually indiscriminate, with curses yelled at anybody within earshot.

In 7 cases informants reported that *baa* subjects did not respond to questions or to attempts to initiate conversation. While the subjects remained mute in response to questions, they did verbalize at other times. This included talking or singing to themselves, yelling curses, or screaming at night.

Three men spoke in a foreign language (English or French) that the local people could not understand. All 3 had become fluent in these languages before becoming *baa*. Speaking in English or French was viewed by peers as a means of excluding them and as a form of snobbishness, since few Lao villagers spoke European languages.

There was one complaint of "not telling the truth." This particular subject did not realize any gains from her supposed lying, and it seems likely that she fabri-

[1] 1969 data provided by the Information Service of the Population Reference Bureau, Washington, D.C.

cated answers in order to respond to people's questions (albeit in a confused fashion), rather than deliberately to provide misinformation.

Socially dysfunctional behavior. This type of behavior was viewed by informants as strange, unexpected, or embarrassing. Such behavior led to social alienation from family and community, although it did not involve violence, crisis, or special problems that demanded social intervention.

There were 34 reports of behavior that was inappropriate to the social context in which it occurred. Such behavior attracted social attention to the subjects and was often an embarrassment to observers or to the *baa* person's family. Examples were as follows:

> When she goes around the town she does a *nob vai* [formal greeting of respect] to everyone, even strangers whom she has never previously seen.

> He pretends he is a famous professor teaching people, telling them historical tales all the time.

> When she goes with the family to dig up roots from the forest, she dresses up in her very best clothes as though she were going to a temple festival. Then if she actually goes to a formal ceremony at the temple, she wears her oldest and poorest clothes.

Nakedness in public was reported for 4 women.

Survival in the villages of Laos requires cooperative effort and dependence on others, since no one person can perform all of the work necessary to ensure individual or group subsistence. Tasks are divided by age and sex. In this milieu, sociability with fellow villagers is accorded high value. In 29 cases there were reports of subjects isolating themselves from others.

> She takes her food away from the table and eats by herself in another room, or she sits down to eat only after the rest have left the room.

> She lives by herself in a lean-to shelter instead of with her family.

> He does not greet even his relatives when he sees them along the road.

Self-neglect, in terms of long-standing inattention to personal cleanliness and grooming, was mentioned as a sign of *baa* behavior for 19 subjects. Most of these subjects had not bathed or groomed for months or even years.

In 11 cases the subjects appeared to work, often with considerable effort repeated over long periods. However, their activities produced no observable economic benefit.

> He always carried 20 or 30 kilograms of scrap iron draped over his shoulders and down his back. He begs for it [the iron], as though he were a monk going around begging for rice. [In Laos Buddhist monks receive ritualized rice offerings each morning at sunrise.]

Impaired psychological function. There were 25 complaints of "wrong ideas" or "false beliefs" that did not conform to reality, descriptions closely approximating the psychiatric definition of delusions. Common examples were as follows:

> He says that someone stole his wife and children, but he has never been married and has no children.

> He thinks that people have put an electric current into him and that they are trying to poison him. He also thinks that people are sending the police after him to harm him.

> He thinks that he might be killed by others, especially at night. So he keeps a knife by his bed, and he keeps the lamp on all night long. He stays awake and vigilant until sunrise.

Informants reported that 9 individuals had "no knowledge" regarding common knowledge or current issues of local or regional concern. This included plans about farming or animal husbandry or popular social issues such as the election of a village chief.

In 5 cases there were reports of an inability to remember things, such as recent occurrences or recent conversations.

Four subjects were reported to have perceptions not observed or validated by others—an equivalent of hallucinations. A typical description was as follows:

> She said that the house smelled bad and ran away. Later she said food smelled bad and threw it away or refused water, saying there was urine in it.

Perceptual disorder was an underreported phenomenon, given our finding from direct questioning and from mental status examination that many *baa* subjects had been or were currently experiencing hallucinations.

There were eight cases in which informants commented on various other items related to intellect. Six included the subject's inability to reason, comprehend, pay attention, or anticipate. Two involved constant worry and recurrent, pessimistic thoughts. Reports included the following:

> He cannot pay attention to anything for more than a few minutes.

> She does not concern herself about anything or make plans for her future.

Affective disturbance. Ten subjects were reported to have frequent, wide swings in mood.

> She is happy, then cries, then laughs, then yells angrily—all in less than an hour.

Constant or frequent anger was reported in 9 cases, sadness or tearfulness in 8 cases, and fearfulness in 5 cases. Examples were as follows:

He is angry all the time, hitting things, throwing things around.

She is very much afraid of dying, especially when it is dark or when there is a thunderstorm.

He sometimes cries for days at a time.

Five subjects showed affect that was not appropriate to their speech or the social context.

He laughs for no reason. When he says, "I'm afraid I'm going to die," he smiles.

Somatic signs and symptoms. Insomnia, which occurred in 19 cases, was the most common complaint and included the full range of sleep disturbances: difficulty falling asleep, restless sleep, early morning wakening, and staying awake all night. In some cases insomnia was noted only early in the *baa* condition, but in most cases it persisted for months or years.

There were 8 cases of weight loss and 2 of weight gain, usually occurring only in the early months of the *baa* condition. Seven subjects were noted to refuse food.

There were 4 cases of weakness; 3 cases each of "red staring eye" or "red face" and temporary "blindness" or "deafness"; 2 cases each of back pain, constipation, convulsions, fatigue, and headache; and 1 case each of "bad feeling in the heart," dizziness, eye pain, inability to swallow, and incontinence of urine or feces.

Family-Community Differences in Folk Diagnosis

Differences in chronology. In 29 cases information on *baa* labeling was obtained from both family and nonfamily members. Twenty-three of these subjects (79%) were socially defined as *baa* by both family and nonfamily members within one year of each other.

In 4 cases (14% of the 29) family and community informants did not agree on the time of onset of the *baa* condition. These 4 cases were diagnosed by the panel of clinicians as "functional psychosis, schizophrenic type." The onset in these cases was gradual rather than acute. In all 4 cases family members reported a longer duration of the *baa* condition than did others (2 years longer in 2 cases and 3 years longer in 2 cases).

Analysis of the 4 cases indicated that behavioral disturbances within the family had been present for 2 or 3 years before unusual events were recognized by the community. These disturbances included throwing food, prolonged crying, and argumentativeness with family members. Three of these four were women who lived within large kinship systems, so that the deterioration in their household and gardening activities was not publicly evident.

Differences in folk diagnosis. Family members and community informants disagreed on the diagnosis in 2 cases (although they agreed on the manifestations and the duration of the condition). These cases involved a 15-year-old woman and a 19-year-old man. Their disorders had been of comparatively short duration (5 and 3 years, respectively). Both subjects belonged to large kinship groups in which most members were literate. Family members devoted considerable time and effort to finding a way to help the *baa* individual. Both of these subjects were diagnosed by the psychiatric raters as having a "functional psychosis, schizophrenic type." The differences in folk diagnosis were in the specificity of labeling by the family members, who considered 1 subject to be suffering from *seah cheet* ("lost heart" or emotional problem) and the other to be *khiet* (a self-centered or "spoiled" adolescent), whereas several community informants defined both subjects as *baa*. In both these instances the family folk diagnosis indicated less disturbance and a more optimistic prognosis.

DISCUSSION

Characteristics of Folk Criteria

The findings of this study demonstrate that folk diagnosis of mental disorder in Laos is made not on the strength of one criterion, but several. In the average case a dozen factors were reported. The presence of only one or a few of these factors was not sufficient evidence to assign a social label of *baa*.

No one criterion was a sine qua non for the *baa* label. However, several criteria were present among at least two-thirds of the 35 subjects. These included socially inappropriate behavior (in 34 of the 35 cases), social isolation (29 cases), inability to work (27 cases), risk of violence to self (26 cases), incomprehensible speech (26 cases), and erroneous ideas or "delusions" (25 cases). Most of the cases were also characterized by some form of affective abnormality, somatic symptoms, and violence against others. These criteria overlap to a considerable extent with folk criteria noted by the anthropologist Edgerton in four East African societies (1) and by psychiatrists Gaviria and Wintrob among Puerto Ricans in Connecticut (2). These investigators noted the following socially disruptive characteristics of mental illness: aggressive behavior, assault, or destruction of property; abusing people verbally or screaming; disorder of thought or communication, such as "talking nonsense"; bizarre behavior and disorders of locomotion, such as "running wildly," going naked, risking injury or injuring self; and disorder of orientation and memory.

Notable by its absence is the lack of reports regarding hallucinations, despite the fact that in the present study hallucinations were found to be present among most of the 35 subjects. Gaviria and Wintrob did not include hallucinations as a folk criterion among Puerto Ricans. In his interviews with 500 East Africans of four different tribes, Edgerton counted only 5 reports of hallucinations among 1,926 responses. Edgerton remarked on the rarity of hallucinations as a criterion,

stating that perhaps hallucinations are "not sufficiently visible to the observer."

A review of these folk criteria from Laos, as well as those reported from other cultural areas, indicates that most criteria are social. Of the 434 criteria in this study, 285 (66%) related to behaviors that are socially dangerous, disruptive, or disturbing. By contrast, only 88 criteria (20%) were psychological; 51 of these involved cognition and 37 affect. Finally, 61 items (14%) involved somatic symptoms. Thus the factors of greatest importance to family and community in assigning a *baa* label were social. This might imply that family and community are apt to see such disorders as primarily social rather than psychological or biomedical. This folk perspective might be a source of conflict with *baa* persons themselves (who are most apt to complain of psychological symptoms or somatic discomfort), as well as with physicians (who may focus on more cognitive and somatic factors).

Behavioral, psychological, social, and somatic criteria were not the only factors that contributed to the *baa* label. There was also variance based on who was applying the label. Generally, family members and community members agreed on the diagnosis; but if differences existed, family members favored diagnoses or labels associated with a more favorable prognosis. This was true despite the fact that the family was usually more affected by the person's condition than was the community and, in some cases, noted the onset of the condition earlier. Edgerton (1) reported a similar, almost fanatical optimism among the family members of a psychotic teenager in East Africa.

Sociodynamics of Diagnosing Insanity

Lao villagers were not overly zealous in applying the term *baa* to their neighbors and family members. On the contrary, they first required evidence of major disability in several areas of functioning. In some cases the signs of disability had to be present for years before the *baa* diagnosis was validated. This observation raises the question, Why was the *baa* social label so reluctantly applied?

From the community's perspective, it was not in the interests of neighbors and family friends to allow anybody to attain the *baa* label. Possession of this social identity allowed certain socially disturbing behaviors that would lead to the person's expulsion from the village if he or she were viewed as sane. Such behaviors included yelling at night and keeping the village awake and assaulting village members and damaging their property. Refusal to accept expulsion from the village or repetition of such behaviors by a sane person could (and sometimes did) end in assassination (11–13). If an individual were defined as *baa*, however, the socially responsible course of action was not exile or assassination. Instead, people were expected to take care of the *baa* individual, hoping for improvement in his or her condition. Consequently, designation of the *baa* label had important implications for the community, just as denial of this identity in the face of certain disturbing behaviors could result in major, potentially divisive social outcomes (such as expulsion or assassination). The social dilemma in such circumstances was not which alternative was all good or all bad, but rather which was least bad.

Family members, perhaps even more than others in the community, appeared unwilling to concede that a person was *baa*. This may be due to the fact that there was more at stake for kin than for nonkin. Since *baa* people often had severe and chronic impairment, the family had to expend time, energy, and material resources in caring for their disturbed relative. They also lost the economic assistance of the *baa* person, who was usually an adult in his or her productive years. While folk etiologies gave no explicit recognition to genetic or family influences in the development of mental illness (14, 15), *baa* kin were a negative factor when marriageability was considered. *Baa* family members also signified a moral stigma for the family, since Lao cosmology explained such misfortunes as punishment for malfeasance by family members.

Edgerton (1) has contended that insanity as a status reduces a person's rights within the social group. That is true to the extent that such people's opinions are not taken seriously and they cannot participate effectively in the political activity of the village. However, the *baa* social identity does give that person the right to be provided with food, shelter, clothing, and humane care despite the fact that he or she is unproductive or underproductive. It also allows an exceptional reprieve from stringent punishments that would be enacted for certain behaviors if the person were considered sane. Thus this identity allows neglect of certain ordinary rights while providing access to other extraordinary rights.

Implications

Studies of folk criteria for mental disorder have made use of several different methods of sampling and data collection (1–9). Investigators have employed their own schemata for classifying their data. In addition, these investigators have come from different countries, as well as from different disciplines. Despite such variation in the studies, the similarity in the findings indicates a number of common features of folk criteria for mental disorder around the world. One interpretation of this similarity is that common explanations of mental disorder—such as spirit possession, soul loss, or divine punishment—have diffused around the world. Another interpretation is that mental disorder—like tuberculosis, cancer, or homicide—has a core biological and/or psychosocial basis. Studies reported thus far do not indicate which interpretation is more likely to be accurate (or whether there are elements of both interpretations). We hope that future systematic research on this subject will provide data that will allow more conclusive cross-cultural comparisons.

β-Endorphin and Naloxone in Psychiatric Patients: Clinical and Biological Effects

BY HEINZ LEHMANN, M.D., N.P. VASAVAN NAIR, M.D., AND NATHAN S. KLINE, M.D.

The authors conducted single- and double-blind studies of the responses of 7 chronic male schizophrenic patients to 10 mg of naloxone. BPRS ratings were made before and 6 hours after the injection; ACTH blood levels were determined before and 1½ and 6 hours after injection. Statistically significant improvement of psychotic behavior occurred after 6 hours. The greatest improvement occurred in the patient who showed the most pronounced diurnal variation of ACTH levels, and there was no improvement in the patient who had no diurnal changes. Prolactin plasma levels following endorphin injections were apparently dose-dependent and peaked at approximately 30 minutes. The mean half-life of elimination of exogenous β-endorphin was between 12 and 35 minutes. The authors theorize that positive and negative behavioral responses to naloxone depend—as possibly do many placebo responses in general—on the relative stress produced by experimental or therapeutic interventions.

THE ENDORPHINS have been called "the body's own opiates" because they attach themselves to the opiate receptors and are specifically displaced from these receptor sites by the opiate antagonist naloxone. Gunne and associates (1) reasoned that if schizophrenia were due to an excess of endorphins, administration of naloxone should reduce schizophrenic manifestations. They found dramatic reduction of hallucinations in 4 of 6 persistently hallucinating schizophrenic patients. Volavka and associates (2), Davis and associates (3), and Kurland and associates (4) failed to confirm these findings.

On the other hand, Emrich and associates (5), in a well-conducted double-blind study, and Berger and associates (6) obtained results similar to those of the Gunne study (1). No explanation has been offered for the absence of response in 2 of the 6 schizophrenics in the Gunne study and in the 8 of 20 patients reported by Emrich and associates (5) who showed less than 5% improvement in the target symptoms of hallucinations, delusions, and ideas of reference and the lack of response of several patients in the Berger investigation (6).

Despite their overall negative reports, Davis and associates (3) noted that the "unusual thought content" item of the Brief Psychiatric Rating Scale (BPRS) was significantly reduced by naloxone. Volavka and associates (2) reported improvement in 2 of 7 patients and Kurland and associates (4) stated that "only 2 of 8" showed complete disappearance of symptoms (compared with 5 of 12 placebo patients).

Could there be a rational explanation of why some patients respond to naloxone and others do not? An equally important but neglected question is how to account for the positive placebo responders.

β-ENDORPHIN RESPONSE HYPOTHESIS

It is our contention that patients should be dealt with as specific individuals rather than being submerged statistically in a group response. Perhaps if this were done it would explain the otherwise anomalous finding that the same individual responds on one occasion but does not do so on another occasion. Placebo responsivity is assumed to be due to suggestibility, conditionability, or other psychological factors, although extensive investigations have failed to establish placebo-responsiveness as an identifiable personality trait.

Our hypothesis is that not only the response to the active substance (in this case, naloxone) but also the placebo response can be accounted for by a measurable physiological factor, i.e., increased endorphin secretion.[1]

Presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8–12, 1978. Received May 22, 1978; revised Jan. 25, 1979; accepted Feb. 23, 1979.

Dr. Lehmann is Professor of Psychiatry, Division of Psychopharmacology, and Dr. Nair is Assistant Professor of Psychiatry, McGill University, Montreal, Que., Canada. Dr. Nair is also Director of Research Services, Douglas Hospital Center, Montreal. Dr. Kline is Director, Rockland Research Institute, Orangeburg, N.Y. 10962.

The authors would like to thank Dr. E. J. Sachar in whose laboratory Ms. Frieda S. Halpern performed prolactin assays and Mr. T. B. Cooper for performing β-endorphin assays and interpreting these data.

[1]We previously had attempted to measure the endorphin levels in patients receiving electroconvulsive therapy or acupuncture or who were under hypnosis, but we found the levels to be below the sensitivity of our radioimmunoassay method. We plan to repeat this work using the ACTH-endorphin yoke index.

Herbert (8), there is a common precursor peptide that gives rise to both adrenocorticotropin (ACTH) and β-endorphin. Guillemin and associates (9) have shown that β-endorphin and ACTH are concomitantly secreted by the pituitary in response to acute stress. They state, "Both hormones possess common and identical regulatory mechanisms . . . ." Thus it seems highly probable that because of the "yoking" of the two peptides, measurement of one would provide an index to the other. Since there is no reported specific technique for measuring β-endorphin at the level at which it is secreted by the organism (i.e., endogenously) but it is possible to measure ACTH levels under such circumstances, we have hypothesized that ACTH levels would be indicative of β-endorphin secretion.

Our hypothesis is that the individuals who clinically improve when given naloxone will have a specific, definable endorphin-response pattern. The stress of intravenous injection may similarly alter the endorphin-response pattern in some patients. Obviously, the same "placebo" factor might affect the patients given naloxone, but, if the drug is active, the test group would have a greater response than the control group.

Incidentally, this might account for Palmour and associates' findings (10). The stress response produced by dialysis (rather than the dialysis of a toxic substance) may alter the β-endorphin-response pattern. It would also account for the response of some patients but not of others, depending in part on the degree to which they are stressed.

The altered β-endorphin response to the stress of naloxone, or dialysis, may be an example of the general altered stress responsivity in schizophrenics to many life events. We believe the research results that follow are compatible with this hypothesis.

STUDY 1—NALOXONE, SINGLE-BLIND

Subjects

The base population consisted of 7 typical chronic schizophrenic patients with florid symptoms. Informed consent was obtained and the study was approved by the institutional review committee.

Patient 1 was a 60-year-old man, diagnosed as chronic schizophrenic, hebephrenic type, who had been continuously hospitalized for the last 30 years. He was regressed and withdrawn, with poor memory and concentration, marked poverty of ideation, and inappropriate affect. He spoke in monosyllables, required supervision in personal hygiene, and periodically refused to eat. He was usually disoriented as to time, place, and person and at times became catatonic.

Patient 2 was a 30-year-old man diagnosed as having paranoid schizophrenia with prominent depressive elements. He was hospitalized at age 23 following a suicide attempt with a rifle. He had only partial insight and poor judgment and was given to neologisms. He had difficulty in producing thoughts and ideas and had paranoid delusions that radio stations were stealing his songs. He admitted to hearing himself on the radio. Occasionally he displayed aggressive behavior toward other patients. The patient was refractory to therapy.

Patient 3 was a 31-year-old catatonic schizophrenic who was first admitted to the hospital at age 16 and had remained hospitalized continuously over the last 7 years. He exhibited periodic outbursts of violent behavior, was preoccupied with a sense of guilt and sought out "punishment," and was slow-moving and had a manneristic walk. He showed some insight, but his general judgment was poor.

Patient 4 was a 53-year-old paranoid chronic schizophrenic who had been hospitalized continuously for the past 16 years. He was well oriented and cheerful, functioned well within the hospital, ate and slept well, and maintained excellent personal hygiene. He was delusional, claiming that he was king of seven countries, and hallucinated virtually all the time, although he was not too troubled by it. A "click signal from God" directed his activities. He laughed inappropriately at times.

Patient 5 was a 28-year-old college-educated man who was diagnosed as paranoid schizophrenic. He was hospitalized for the first time five years previously after attempting suicide by jumping out of a moving car. He was well oriented but exhibited thought blocking, looseness of association, thought insertion, and diffusion. He talked a great deal about his "worthlessness," for which he felt depression and guilt. He had the delusions that there was a "machine in my brain" and that the staff was attempting to poison him. He had blunted affect and frequent auditory hallucinations.

Patient 6 was a 46-year-old man who was diagnosed as paranoid schizophrenic. He had been in and out of

ACTH Plasma Levels Before and After Naloxone or Placebo Injection

Patient Number	ACTH Level (ng/ml) With 10 mg Naloxone: Pre-injection	After ½ Hour	After 6 Hours	With Placebo: Pre-injection	After ½ Hour	After 6 Hours
1	61	59	56	58	53	64
2	40	85	60	44	54	31
3	106	41	33	74	39	28
4	38	28	40	25	5	18
6	32	28	24	—	—	—

hospitals since 1960 and continuously hospitalized during the past six years. He had no insight and poor judgment and was suspicious, anxious, withdrawn, and occasionally verbally and physically aggressive. He had delusions such as having a million dollars in the bank, required minimal supervision of personal hygiene, and had occasional tactile and olfactory ("fish smell") hallucinations and frequent auditory hallucinations, which he claimed caused pain in his legs and made his heart stop.

Patient 7 was a 42-year-old man, chronic schizophrenic of the residual type, who had first been hospitalized when he was 16. He had no spontaneity of expression, was withdrawn, and had slow monotonous speech, blunted affect, and disordered thought processes. He had no insight and poor judgment and answered questions irrelevantly with "O.K., Mother," smiling inappropriately.

Method

Six patients were given 10 mg of naloxone intravenously and evaluated at baseline (immediately before injection) and at 3, 6, and 24 hours after injection. The evaluation used was the Brief Psychiatric Rating Scale (BPRS). Four of the same 6 patients were also evaluated in the same manner after saline injections.

The 10-mg dose of naloxone was selected because some investigators have been criticized for giving the therapeutic dose of .4 mg, which has been judged to be inadequate to produce a full response. There is also evidence that the optimal response of schizophrenics does not occur until approximately 6 hours after naloxone administration, which was confirmed in our study and was therefore the time for which evaluation is reported. Further, since Frederickson and associates (11) showed that naloxone-induced hyperalgesia in mice follows a diurnal rhythm, all subjects were given naloxone at 8 a.m.

Results

Six hours after injection there was a statistically significant reduction on the tension item of the BPRS (see table 1). Three of the 6 patients given saline placebo showed a nonsignificant increase on this item.

STUDY 2—NALOXONE, DOUBLE-BLIND

Five of the 7 patients described in study 1 served as subjects in this study. Naloxone and saline placebo were again given, using the same dose, method, and time of evaluation as in study 1.

Interestingly, the findings were more significant than in the single-blind study. The total BPRS score, the thought disturbance factor, and the hallucinatory behavior item were each significantly improved (see table 1).

STUDY 3—PLASMA ACTH LEVELS

The plasma ACTH levels of 5 patients were determined by radioimmunoassay. A relationship between plasma ACTH levels and clinical response was manifest in that the patient who showed no diurnal variation in ACTH level was clinically least responsive to naloxone (patient 1). Conversely, the subject (patient 3) who showed the greatest variability of ACTH levels (diurnal drop) showed the greatest clinical improvement (see table 2).

There has been much discussion of the criteria for selection of patients for naloxone studies. Watson and associates (12) stated that naloxone response is limited to a very small subgroup of continuously and vividly hallucinating schizophrenics. They screened 1,000 patients to obtain a "suitable" sample of 11 subjects. Our own results would indicate that much less rigid criteria can be used. The 5 patients we used were selected from a group of 40, using 3 criteria: hallucinations, thought disorder, and dysphoria.

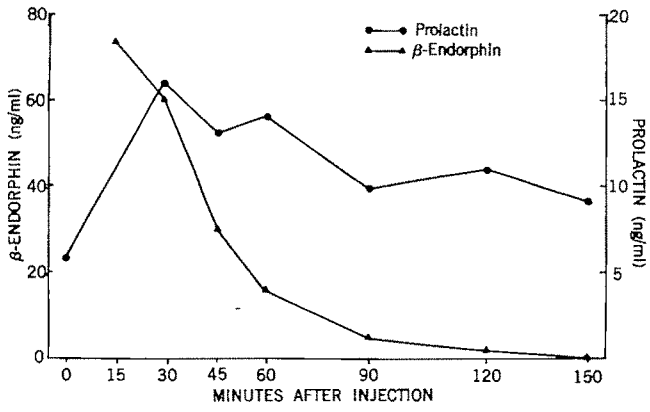
We do not know what response would occur in the other schizophrenics. Perhaps they too would show improvement; even our more liberal criteria may be too restrictive. In the future, investigators might consider using random selection of schizophrenics or perhaps of all psychiatric patients, to determine what limitations, if any, would apply.

STUDY 4—PROLACTIN RESPONSE TO β-ENDORPHIN AND PLASMA HALF-LIFE OF β-ENDORPHIN

The base population for this study has been described elsewhere (13, 14).

Selected blood samples from our β-endorphin studies (13, 14) were analyzed for prolactin content. Figure 1 shows plasma levels in 1 patient from whom blood samples were collected before infusion and at frequent intervals after an infusion of 6 mg of β-endorphin. The prolactin response apparently peaks at approximately 30 minutes, at which time values close to three times those of baseline are observed. Figure 2 shows the percent of baseline levels of prolactin after injection in the same patient, in a patient given 3 mg of β-endorphin initially and another 3 mg of β-endorphin 165 minutes

FIGURE 1
Prolactin and β-Endorphin Plasma Levels In 1 Patient After Injection of 6 mg of β-Endorphin



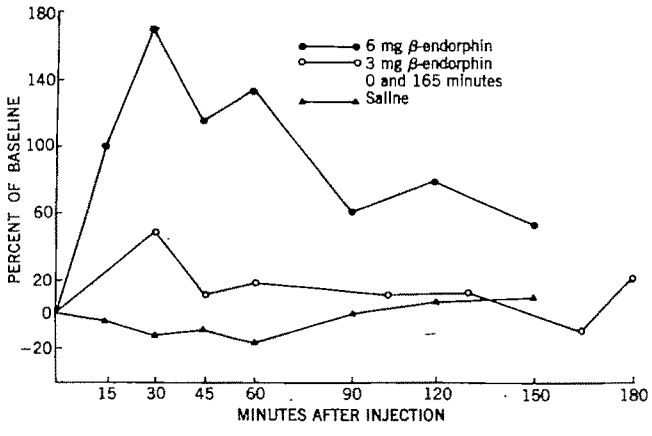


FIGURE 2
Prolactin Plasma Level Response to β-Endorphin and Saline Injection

later, and after saline infusion (control data and 3-mg β-endorphin data were obtained from the same patient).

Blood samples were collected by means of a butterfly in a vein in the antecubital fossae. The samples were collected preinjection and 15, 30, 45, 60, 90, and 120 minutes postinjection. These samples were immediately placed in iced water and kept in the cold until centrifuged (refrigerated centrifuge) and the plasma frozen.

We did 6 subject experiments in which single bolus injections of 3–9 mg of β-endorphin were given. These data were readily fitted with a single exponent. The mean half-life of elimination calculated from these data was 19.6 minutes (range, 12–35 minutes).

Preliminary attempts to measure endogenous levels of β-endorphin in these patients have not proved successful, which indicates that endogenous levels in humans, if present, are in the picogram per milliliter range.

DISCUSSION

We have three-fold evidence suggestive of a role of endorphins in depression: 1) Kline and associates (13, 14), 2) Angst and associates (15), and 3) Terenius and associates (16). All three of these studies point to a deficiency of endorphins in the depressed patient.

The role of endorphins in schizophrenia is much less clear. Indirect evidence that the endorphins are noxious is attested to by the fact that naloxone—in some patients but not all—produces improvement under certain conditions. The three leading hypotheses on the role of endorphins in schizophrenia are 1) that there is an excess, 2) that there is a deficiency, or 3) that there is an aberrant form, possibly a false transmitter. These hypotheses are not mutually exclusive.

Our own findings with intravenous injections of β-endorphin to schizophrenic patients indicate that the therapeutic phase, when it occurred, was delayed one to three days in onset. This time lag is not unlike that of ECT and the phenothiazines and related antipsychotic agents. Compatible with this is the demonstration that β-endorphin is increased in phenothiazine-treated animals only after prolonged administration (17).

The most unique feature of the clinical response of some schizophrenic patients to β-endorphin appeared to be the restructuring of a healthy personality that continued to develop even after endorphin was no longer administered. This went beyond the mere suppression of symptoms and recalled the ancient concept of *vis medicatrix naturae*, set in motion by the endorphin (reminiscent of the German "Stosstherapie").

We believe that it is premature to construct an all-encompassing theory, but at the same time we do feel that theoretical bridges between apparently disparate findings should be encouraged. They may in turn give rise to crucial experiments that will provide hard data to further expand our understanding.

Gonadotropin, Estradiol, and Testosterone Profiles in Homosexual Men

BY STEPHEN R. NEWMARK, M.D., LESLIE I. ROSE, M.D., ROBERTA TODD, M.S., LEE BIRK, M.D., AND FREDERICK NAFTOLIN, M.D., D.PHIL.

The authors evaluated the gonadotropin-testosterone-estradiol profiles of four homosexual men and four heterosexual men by a multiple-sampling technique. Although there was extensive overlap between the two groups, the homosexual subjects had higher estradiol levels than the heterosexuals (70.3 ±19.8 versus 56.8 ±10.7 pg/ml) and lower FSH values (5.1 ±1.0 versus 13.2 ±3.4 mIU/ml). Testosterone and luteinizing hormone levels were comparable in the two groups. These observations suggest that there may be subtle differences in gonadotropin and estradiol secretion in homosexual subjects that can be detected only by repeated sampling.

RECENTLY there has been renewed interest in the relationship of the endocrine system to homosexuality, and results have been conflicting in some cases (1–5). Because pituitary gonadotropins (6), testosterone (7), and estradiol (8) are secreted in a pulsatile manner, a single blood sample may not accurately reflect hypothalamic-pituitary-testicular activity—the levels may vary several-fold over any sampling period. In the present study, a multiple-sampling technique over several hours was used to determine whether the gonadotropin-testosterone-estradiol profile of homosexual subjects differed from that of heterosexual male control subjects.

Parts of this paper were presented at the Southern Section, American Federation for Clinical Research, New Orleans, La., Jan. 26, 1976. Received May 25, 1977; revised Jan. 25, 1978; accepted March 29, 1978.

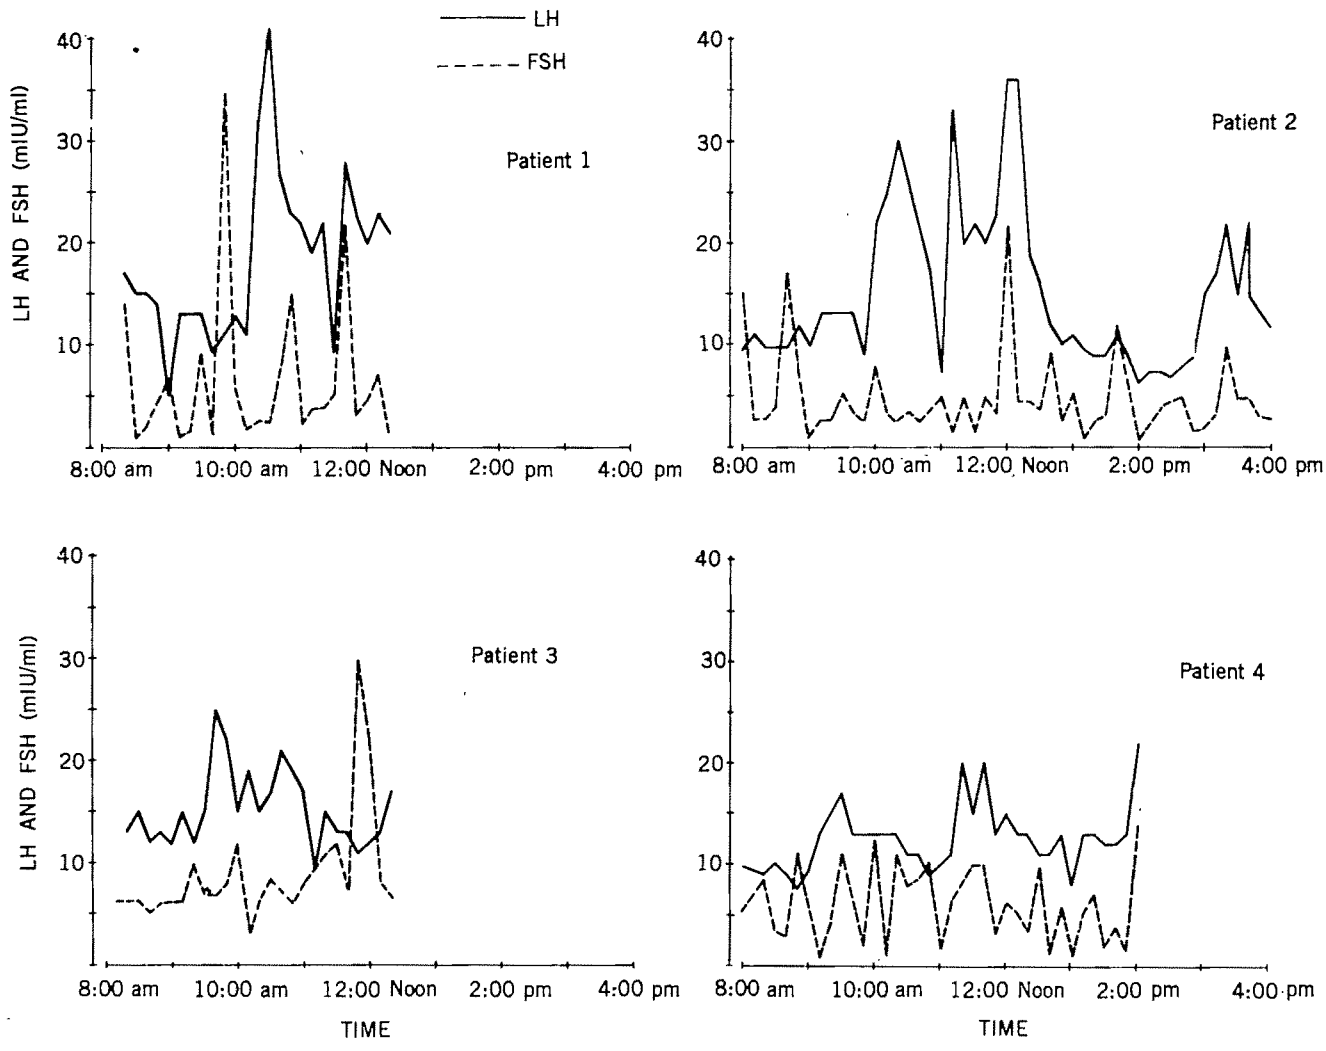
METHOD

The four male homosexual subjects were psychotherapy patients ranging in age from 22 to 30 years. Each patient was assigned a Kinsey number (9) based on his own assessment of his homosexual/heterosexual feelings plus a therapist's evaluation after several hours of interviewing. Subjects' and therapists' ratings were identical (all Kinsey number 6, or exclusively homosexual) in all four cases.

The four control subjects, aged 21–29, were considered to be heterosexual on the basis of a history taken by two interviewers. All subjects received a physical examination and detailed histories were elicited. Laboratory examination included X-rays of the chest and sella turcica, ECG, CBC, urinalysis, electrolytes, liver function tests, thyroxine, fasting blood glucose, and creatinine. All subjects denied a recent use of medications or drugs, including marijuana.

Blood samples were taken from an antecubital vein via an indwelling catheter every 15 minutes for 4–8 hours. Serum was frozen at −20°C until hormone assay. Subjects reclined during the study.



Serum gonadotropins (10, 11) were estimated by specific radioimmunoassay using the Second International Reference Preparation as a standard. Testosterone was measured by the method of Niswender and associates (12). Estradiol was determined by the method of Korenman and associates (13). Progesterone, androstenedione, estrone, and dihydrotestosterone were determined by the method of Challis and associates (14).

The standard errors of the assays (intraassay variations) were as follows: follicle-stimulating hormone (FSH), 2%; luteinizing hormone (LH), 2%; testosterone, 8%; estradiol, 5%; progesterone, 7%; androstenedione, 10%; estrone, 10%; and dihydrotestosterone, 10%. To eliminate interassay variation, all samples were assayed simultaneously in duplicate for each hormone being measured.

Semen analysis was determined by standard methodology (15). Free estradiol was determined by the method of Tulchinsky and Chopra (16). Two serum samples were tested from each patient. Data were analyzed by Student's t test (two-tailed).

FIGURE 1
Serum FSH and LH Levels Obtained Every 10 Minutes in Homosexual Subjects

RESULTS

The FSH and LH values were examined by determining means for all samples. To minimize the effect of the variation in FSH and LH levels that results from pulsatile secretion, a log transformation was performed on each group and the means of the log transformation of FSH and LH values per 4 hours were also analyzed (17).

Gonadotropin pulses in serum were determined for each individual and were considered to reflect secretion (18). A pulse of FSH or LH was defined as an increase of 5 mIU or greater that was present for at least two consecutive determinations. The termination pulse was defined as a decrease of 5 mIU in at least two consecutive determinations. Both groups had multiple pulsatile secretion of gonadotropins (figures 1 and 2). Both groups had 0.8 FSH pulses/hour, and the heterosexual group had 0.8 LH pulses/hour as opposed to 0.6 pulses/hour for the homosexual group, a non-significant difference ($.05<p<.10$). The LH values for the heterosexual group and the homosexual group were not statistically different (see table 1). However, FSH values were significantly lower in the homosexual group.

Serum testosterone and estradiol levels were obtained hourly (figures 3 and 4). Although serum testosterone levels were similar in both groups, serum estradiol levels were significantly higher in the homosexual group (see table 2). The values for testosterone and estradiol are higher than the usual reported levels for normal subjects, but they have been consistent in our laboratory.

Single random samples of estrone, progesterone, dihydrotestosterone, and androstenedione levels were similar in both groups, although the mean progesterone level of the homosexuals was almost twice that of the heterosexuals (table 2). The percentage of total estradiol as free estradiol was significantly lower in the homosexual group ($p<.05$), although the calcu-

Steroid Hormone Levels in 4 Homosexual and 4 Heterosexual Men

Assay[a]	Homosexual Mean	SD	Heterosexual Mean	SD	p
Testosterone (ng/100 ml)	986.2	273	882	102.6	n.s.
Estradiol (pg/ml)	70.3	19.8	56.8	10.7	<.025
Unbound estradiol (pg/ml)	2.4	0.1	2.1	0.1	n.s
Unbound estradiol (%)	3.3	0.3	3.8	0.4	<.05
Androstenedione (ng/100 ml)	118.9	48.5	100.6	31.2	n.s.
Progesterone (ng/100 ml)	93.0	39.2	58.9	18.6	n.s.
Estrone (pg/ml)	130.4	19.3	125.4	38.2	n.s.
Dihydrotestosterone (ng/100 ml)	46.4	12.9	44.1	6.2	n.s.

[a]Testosterone and estradiol values are means for all samples; androstenedione, progesterone, estrone, and dihydrotestosterone are group means, with 1 sample per subject.

lated mean free estradiol was the same for both groups.

Sperm count and morphology were similar in both groups and were all above $40 \times 10^6/mm^3$, with normal morphology and motility at 2 hours.

DISCUSSION

In recent years there have been extensive reports on the relationship of the endocrine system to male homosexuality. Kolodny and associates (1) reported lower plasma testosterone values, impaired spermatogenesis, and higher FSH and LH levels in a group of 30 homosexual patients compared to a matched group of heterosexual individuals. The elevated LH values were correlated with decreased plasma testosterone values, and the elevated FSH values were seen in men with oligo or azospermia. These abnormalities were most pronounced in those homosexuals who had higher homosexual scale values on the Kinsey rating system. Others (2–5) have demonstrated normal values for plasma testosterone and suggested that the differing endocrine profiles probably are secondary to several factors, among which are sample size, differing etiologies of homosexuality, and effects of therapy. Doerr and associates (4) reported increased plasma estradiol levels in homosexual patients without concurrently decreased plasma testosterone levels or sperm counts. All of the previous studies were based on a single sample from the subject population.

Since values for serum gonadotropins, estradiol, and testosterone vary dramatically, as shown by frequent sampling, the FSH-LH-sex steroid profile is more accurately determined by a multiple-sampling technique.

It can be seen readily (figures 1 and 2) that both subject groups had multiple secretory episodes of FSH and LH, as determined by multiple sampling. Although the LH means were identical in both subject groups, the FSH means were substantially lower in the homosexual group. This would imply that although FSH is being secreted in pulsatile form, the total amount secreted is less than in the heterosexual group; nevertheless, there is considerable overlap of the individual values in both groups. It is not apparent why FSH secretion is low in the homosexual group. One possibility is that the elevated serum estradiol in the homosexual group selectively impairs the pituitary secretion of FSH in response to endogenous hypothalamic releasing hormones; selective estrogen-induced inhibition of FSH secretion has been demonstrated elsewhere (15). Other possibilities include altered metabolic clearance of FSH, altered metabolism, or increased "inhibin" secretion (15).

Serum testosterone values were similar in individuals from both study groups, as were single samples assayed for dihydrotestosterone, androstenedione, progesterone, and estrone. Serum testosterone values displayed variations each hour (figure 3) that were presumably secondary to intermittent secretion by the testes or to altered metabolic clearance rates. The lack of correlation with FSH or LH levels or pulses could be due to the difference in the timing of the sample measurements.

The total mean serum estradiol value was increased in the homosexual group, although individual values in both subject groups overlapped (figure 4). This could reflect increased testicular secretion, increased conversion of androgen precursors, increased sex hormone binding globulins, or decreased metabolic clearance. None of these has been studied in homosexual males.

The percentage of free or unbound estradiol was significantly lower in the homosexual group. This presumably reflects higher endogenous binding proteins and may explain why the serum estradiol values are increased in the homosexual group. However, it is also possible that the increase in binding proteins is secondary to increased estradiol secretion. There is cur-

rently no way to distinguish between these two alternatives. Total unbound estrogen levels are comparable in the two groups. As unbound estradiol is presumably the active component of the steroid, it is possible that the elevated total estradiol level in the homosexual subjects does not have a biologic effect on them.

It is important to note that all four of the homosexual subjects were receiving psychotherapy, whereas the four control subjects were not in psychotherapy. The relationship between psychotherapy, mental illness, and endocrine status remains to be clearly defined. It is therefore possible that some of the endocrine changes demonstrated might be related to psychotherapy or affective state rather than homosexuality. Further studies are necessary to clarify these relationships.

At present, one cannot conclude that there is a basic or causative alteration in endocrine control systems in the male homosexual. Nevertheless, evidence is beginning to accumulate that, at least in some homosexual individuals, there are significant differences in the levels of gonadotropins and either estradiol or testosterone; however, because of individual variation or pulsatile secretion, a single blood specimen may not reflect an endocrine abnormality.

Choline and Lecithin in the Treatment of Tardive Dyskinesia: Preliminary Results from a Pilot Study

BY ALAN J. GELENBERG, M.D., JOANNE C. DOLLER-WOJCIK, R.N., M.S., AND JOHN H. GROWDON, M.D.

Tardive dyskinesia is thought to reflect increased dopaminergic activity of the central nervous system. To compensate for this by increasing CNS cholinergic tone, the authors administered oral choline and its natural dietary source, lecithin, to 5 men with mild to severe tardive dyskinesia in a nonblind trial. Both choline and lecithin increased serum choline levels and improved abnormal movements in all patients. Lecithin had fewer adverse effects.

TARDIVE DYSKINESIA is a disorder of abnormal involuntary movements associated with the ingestion of neuroleptic drugs (1). A popular hypothesis is that tardive dyskinesia involves an imbalance in the postulated reciprocal relationship between dopaminergic and cholinergic neurons in the basal ganglia (2–4). This imbalance appears to favor dopamine transmission at the expense of acetylcholine transmission—the biochemical obverse of Parkinson's syndrome. The relative dopamine excess may result from increased dopamine turnover (5) or from a denervation type of supersensitivity (6).

Consistent with this hypothesis of the neurophysiology of tardive dyskinesia are observations that drugs which block catecholamine synthesis (alpha-methylparatyrosine) (3, 7), deplete the brain of monoamines (reserpine, tetrabenazine) (8), or antagonize dopamine's action on synaptic receptors (phenothiazines, haloperidol) (9) often suppress tardive dyskinesia, whereas drugs that indirectly stimulate dopamine receptors (amphetamine, L-dopa) (10, 11) can increase the abnormal movements. In attempts to increase central nervous system (CNS) cholinergic tone, deanol, a putative choline precursor, has been administered to patients with tardive dyskinesia, but the results have been variable (11–15). In a similar vein, physostigmine, a centrally active anticholinesterase drug, has been administered intravenously to patients with tardive dyskinesia, with resultant decreases in choreic movements (16, 17). A third strategy for increasing CNS cholinergic tone is the administration of choline chloride and the natural dietary source of choline, lecithin. In this paper we will report the preliminary results of a nonblind pilot project in which choline and lecithin were administered to outpatients with mild to severe tardive dyskinesia.

Revised version of a paper presented at the New Clinical Drug Evaluation Unit Meeting, Key Biscayne, Fla., May 23–25, 1978. Received July 19, 1978; revised Nov. 10, 1978; accepted Feb. 23, 1979.

Dr. Gelenberg is Assistant Professor of Psychiatry, Harvard Medical School, Boston, Mass. He is also Chief, and Ms. Doller-Wojcik is Nursing Coordinator, Special Studies Clinic, Erich Lindemann Mental Health Center and Massachusetts General Hospital, Boston, Mass. 02114. Dr. Growdon is Assistant Professor of Neurology, Tufts University, Medford, Mass.

The authors wish to thank Carolyn Widen, L.P.N., for her assistance with patients; the staff of the Harbor Area Mental Health System for their support; and Ms. Emily Newkirk-Prins for her help with the manuscript.

METHOD

Patients

Ten patients have entered the study to date. In this paper we will present data on 5 of them. Three other patients are still in early phases of treatment, and data are not yet available. The remaining 2 patients were dropped from the study, 1 because of poor compliance and the other because further neurological testing revealed basal ganglia disease believed to represent a process other than tardive dyskinesia.

The 5 patients to be discussed here were treated with both choline and lecithin. All 5 were men, ranged in age from 27 to 32, and were outpatients. Two were given a diagnosis of schizophrenia; 1, severe obsessive-compulsive neurosis; 1, chronic anxiety; and 1, chronic depression.

Stable signs of tardive dyskinesia had been present for 1–5 years, onset was well documented in all cases, and global severity of movements was rated from mild to severe and agreed to by both the project psychiatrist (A.J.G.) and the project neurologist (J.H.G.). The diagnosis of tardive dyskinesia was based on the following criteria.

1. Abnormal involuntary movements of a choreoathetotic, dyskinetic variety were present in the mouth, face, and/or extremities.
2. The movements occurred in patients who had been treated with an antipsychotic drug for at least 6 months.
3. Abnormal movements appeared either while the patient was receiving an antipsychotic drug or within 4 weeks after discontinuation of such medication.

0002-953X/79/07/0772/05/$00.50 © 1979 American Psychiatric Association

Attempts were made to rule out naturally occurring forms of extrapyramidal disorders, other forms of drug-induced extrapyramidal disorders, and schizophrenic mannerisms and stereotypies.

Procedure

After giving written informed consent, patients were started on choline chloride, 150 mg/kg per day, in three divided doses. Dosages were then adjusted based on clinical response and adverse reactions, to a maximum of 200 mg/kg per day. Once a stable dose was reached, an attempt was made to maintain patients on choline for 6–8 weeks. A 2-week washout period was then planned, but for practical reasons it varied from 18 days to 5 weeks. After washout, patients were begun on lecithin, with an initial daily dose for all patients of 21 g in three divided doses. The dose of lecithin was increased at weekly intervals to as high as 105 g/day. Choline was supplied as a powder, which patients mixed in sweet beverages such as fruit drink or soda pop; lecithin was supplied in the form of granules that contained 20% phosphatidylcholine and was mixed with or sprinkled on apple sauce, yogurt, or ice cream.

Dyskinetic movements were rated weekly on the NIMH Abnormal Involuntary Movement Scale (AIMS) (18), frequency of movements was counted over 30 seconds, and patients were videotaped. Parkinsonian signs were also rated at weekly intervals using the Targeting Abnormal Kinetic Effects (TAKE) Scale (a scale we have devised as a comparison piece to the AIMS) and Simpson-Angus Scale (19), psychiatric state was evaluated with the Brief Psychiatric Rating Scale (20) and Clinical Global Index (21), and side effects and patients' subjective global assessments were also recorded. Laboratory testing included electrocardiograms, complete blood count, urinalysis, and serum enzyme and lipid profiles. Serum choline levels were assayed before treatment, during choline therapy, and again during lecithin therapy using a radioenzymatic method (22).

Patients were allowed to continue to take other medication (except anticholinergic agents), and these were maintained at relatively constant doses.

RESULTS

Table 1 summarizes patient responses. The AIMS scores and percentage changes are based on average weekly ratings of body parts that showed at least mild abnormal movements at baseline assessment. The AIMS assessments, performed by a trained nurse-rater (J.D.W.), were reliably correlated with neurologist-rated (J.H.G.) movement-counts; this will be discussed further in a future communication.

As the table indicates, all of the patients improved on both treatments, with a tendency toward greater improvement on lecithin. During the washout period the patients' movements began to worsen within several days, and most had returned to baseline levels between 1 and 2 weeks.

Daily doses of choline chloride ranged from 12 to 17 g, and maintenance doses from 12 to 14 g. Two subjects (patients 4 and 5) discontinued lecithin prematurely for reasons listed below. Patient 5 received lecithin for only several days, so his lecithin response is not indicated in table 1. Patient 4 received lecithin for 8 weeks, but both his daily lecithin dose and serum choline increase were considered suboptimal (see table 2). The remaining 3 patients have continued to receive 105 g of lecithin daily for up to 6 months without evidence of tolerance to the therapeutic benefit.

Four of the 5 patients continued to receive phenothiazine therapy throughout the study. Patient 1 had ingested no antipsychotic medication for 4 months before the study. Patient 2 had received fluphenazine hydrochloride, 10 mg per day, for 6 months before the study. During the last month of the study his fluphenazine was decreased to 5 mg daily and his overall AIMS scores worsened somewhat, with an increase in the average lecithin AIMS score and a decrease in the average percentage improvement on lecithin therapy. Patient 3 had received fluphenazine hydrochloride, 40 mg daily, for 3 months before the study, and this schedule was maintained throughout the study period. Patient 4 was taking fluphenazine, 10 mg daily, for 1 month before the study, and this was discontinued 1 week before the end of the lecithin trial; the discontinuation did not appear to affect his AIMS scores, however. Patient 5 had been receiving a stable dose of trifluoperazine, 40 mg daily, for $2\frac{1}{2}$ months before and during the study. During his last 3 weeks of choline therapy trifluoperazine was reduced to 30 mg a day; the change in dosage was accompanied by transient increases in abnormal movements.

The patients' serum choline levels are presented in table 2. The table illustrates that both choline and lecithin are capable of producing considerable increases in serum choline levels.

All 5 patients found the bitter taste of choline unpleasant. Furthermore, all developed a distinctive and unpleasant "fishy" body odor after several days on the higher doses of choline. Each patient also developed symptoms of gastrointestinal irritation on choline, and this was often a dose-limiting factor. There was a tendency toward the appearance of or an increase in parkinsonian signs (such as bradykinesia, tremor, and rigidity) during both treatments, but this side effect was mild and transient. The only adverse reaction specifically attributed to lecithin was a 7% increase in body weight in 1 patient. Lecithin did not produce a body odor, and the patients found its addition made food more palatable, rather than less so. No changes in laboratory test values occurred in any patient during the study.

There were no consistent changes in patients' mental status. Two subjects (patients 4 and 5) discontinued lecithin because of increasing paranoia, but the paranoia was not improved in either patient several weeks

TABLE 2
Serum Choline Levels of 5 Men with Tardive Dyskinesia

Item	Serum Choline Level (nmol/ml)
Patient 1	
Pretreatment	15.2
Choline (17 g/day)	48.4
Lecithin (105 g/day)	43.2
Patient 2	
Pretreatment	12.2
Choline (19 g/day)	22.0
Lecithin (77 g/day)	24.0
Patient 3	
Pretreatment	7.1
Choline (19 g/day)	36.3
Lecithin (105 g/day)	21.7
Patient 4	
Pretreatment	10.5
Choline (8 g/day)	17.1
Lecithin (21 g/day)	13.3
Patient 5	
Pretreatment	12.0
Choline (8 g/day)	27.3

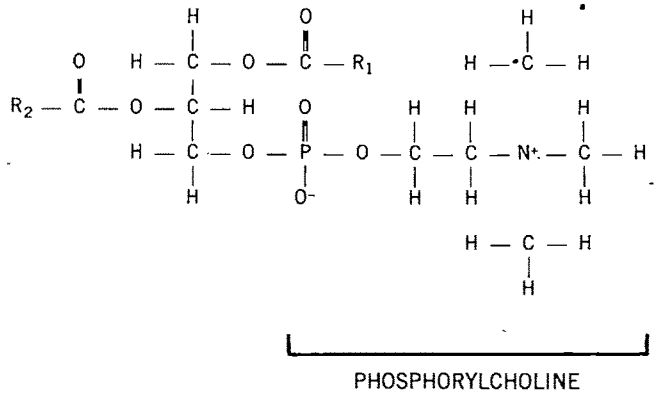
after discontinuation of the drugs. Two patients were noted to be slightly more depressed during the study, but 2 other patients showed a marked improvement in preexisting depression.

DISCUSSION

Choline is the physiological precursor of acetylcholine (23), which is synthesized by combining molecules of choline and acetylcoenzyme A in a reaction catalyzed by the enzyme choline acetyltransferase. Choline-induced increases in acetylcholine levels in the brain appear to reflect increased synthesis (24) and also cause increases in acetylcholine release onto postsynaptic sites (25). The brain is unable to make choline de novo and extracts it instead from the systemic circulation by a low-affinity uptake process that is normally unsaturated (25). The enzyme choline acetyltransferase, which converts choline to acetylcholine,

is also unsaturated with the circulating precursor in vivo, and increasing the amount of substance increases the net catalytic activity of the enzyme. Thus Cohen and Wurtman showed that choline, by injection (26) or dietary supplementation (24), increased blood choline, brain choline, and brain acetylcholine levels in the rat, and these findings were confirmed independently by Haubrich and associates (27). Choline administration also caused parallel increases in acetylcholine release, as judged by biochemical changes in cells that are postsynaptic to the cholinergic neuron. Thus choline administration increased tyrosine hydroxylase (the rate-limiting enzyme in cathecholamine synthesis) in both the adrenal medulla (28) and the caudate nucleus (29); prior atropine administration or denervation of the splanchnic nerve to the adrenal gland blocked this effect.

In clinical studies Davis and associates (23) described a man in whom the administration of choline (16 g per day) decreased the choreiform movements of tardive dyskinesia. This group and others (30, 31) have since reported additional evidence that choline can diminish the movements of tardive dyskinesia. Growdon and associates (32) reported that in a double-blind crossover study involving 20 patients with tardive dyskinesia, blood choline levels in all patients increased during choline ingestion, and 9 patients were significantly improved.



Choline in blood derives normally from two sources: dietary consumption (primarily as lecithin in egg yolk, soy beans, fish, meat, and many other foods) (33) and from synthesis in liver (34). Lecithin, the usual dietary source of choline, consists of choline covalently bound to glycerol and fatty acids (see figure 1).

The therapeutic use of choline presumably derives from the ability of orally administered choline to markedly elevate plasma levels in humans (35). Studies in normal humans indicate that the administration of large oral quantities of lecithin causes an even greater and longer-lasting increase in serum choline levels (36). In rats, oral lecithin has also been shown to increase brain choline and acetylcholine levels (37).

The data from this nonblind, uncontrolled study support earlier findings that choline chloride can alleviate some of the signs of tardine dyskinesia. This study extends these findings to a less severe, younger, and less chronic population. Furthermore, lecithin therapy appears to be at least as effective as choline, with fewer adverse reactions and greater patient acceptance; these findings were recently confirmed by Barbeau (38). Moreover, some of our patients have received lecithin at doses greater than 100 g daily for over 4 months with no evidence of ill effects.

Thus far our data can neither confirm nor refute reports that choline (and presumably lecithin, also) can cause clinical depression (31). If the cholinergic-adrenergic hypothesis of mood regulation is accurate (39), an increase in CNS cholinergic tone might certainly be expected to produce or worsen depressive symptoms. Yet if data from reserpine therapy can serve as an analogy, perhaps choline can be expected to produce depression in, say, 10% of the population with a depressive diathesis (40). This question remains open at the present time.

FIGURE 1
Structure of Lecithin

The worsening of parkinsonian signs that we observed is certainly consistent with the well-accepted dopamine-acetylcholine balance theory (41).

Since lecithin is able to achieve increases in blood choline levels, and presumably brain acetylcholine levels as well, and because our data suggest that lecithin administration can produce clinical improvement with fewer adverse reactions, we plan to discontinue further clinical use of choline chloride. We also plan to use a lecithin preparation with a higher concentration of phosphatidyl choline, thereby lowering the amount of extraneous lipids ingested. In the near future we expect to withdraw our patients from lecithin therapy and treat the responders in a double-blind, placebo-controlled, crossover design to further assess the positive responses. Future research will involve prospective, double-blind trials of large numbers of patients with tardive dyskinesia.

If the results of this pilot study are confirmed, several benefits will be realized. Headway will have been made toward the realization of therapy for patients with tardive dyskinesia, a troublesome and common long-term, irreversible reaction to antipsychotic drugs. In addition, we will have achieved further understanding of the mechanism of tardive dyskinesia in particular and basal ganglia disease in general. Finally, a dietary constituent will have been shown to affect the levels of a CNS neurotransmitter, opening possibilities for a greater understanding of normal neurophysiology and for future therapies.

Hysterical Psychosis and Hypnotizability

BY DAVID SPIEGEL, M.D., AND ROBERT FINK, M.D.

The very existence of hysterical psychosis as a diagnostic entity has been questioned as part of the general difficulty in defining both hysteria and psychosis. However, several recent investigations have documented a syndrome that usually involves brief and intense periods of psychotic behavior, generally with graphic decompensation, severe environmental stress, and rapid recompensation, in individuals with other hysterical features. The authors assert that such a syndrome does exist as a clinical entity and that the differential diagnosis can be facilitated by using a standardized measure of hypnotic trance capacity. They hypothesize that patients with hysterical psychosis are highly hypnotizable, while those who are schizophrenic and psychotic have low hypnotizability. The authors review the literature and present two case examples.

FOR A FLORIDLY psychotic patient with delusions, loose associations, ideas of reference, and inappropriate affect, the standard differential diagnosis must include schizophrenia, an affective disorder of psychotic proportions, and various toxic and organic disease states. Another clinical entity that deserves consideration in this differential diagnosis is hysterical psychosis. Such individuals often experience rapid and florid psychotic decompensation, including delusions, ideas of reference, loose associations, and affect that can range from bland indifference which approaches flatness to intense agitation. They may or may not have a family history of thought disorder and often mobilize tremendous attention and anxiety in their social network. They frequently have a history of good premorbid adjustment and may not respond to neuroleptic medication (i.e., they are sedated but do not improve). They can be distinguished from schizophrenic patients who are experiencing a psychotic episode by psychological testing and careful evaluation of history and affect. The intact capacity for repression implied by *la belle indifference* in hysteria contrasts with the flatness traditionally associated with schizophrenia. Further, a standardized assessment of hypnotizability, the capacity to enter a hypnotic trance state, is a useful device for confirming the differential diagnosis of schizophrenia versus hysterical psychosis. According to this criterion, individuals with hysterical psychosis are generally highly hypnotizable, except perhaps during periods of intense agitation, while those with schizophrenia show little or no hypnotizability.

Received May 19, 1977; revised June 9, 1977, and April 28, 1978; accepted May 18, 1978.

Dr. Spiegel is Assistant Professor of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, Calif. 94305, and Director of Social Psychiatry/Community Services, Palo Alto Veterans Administration Medical Center. When this paper was written, Dr. Fink was Resident in Psychiatry, San Mateo County Mental Health Program; he is currently Medical Director, Island Mental Health Centers, Whidbey Island, Washington.

This work was supported in part by research funds from the Veterans Administration.

The authors thank Donnel Stern, Ph.D., Edward Detrick, Ph.D., and Richard Poe, M.D., for reviewing the manuscript.

LITERATURE REVIEW

Charcot is famous for (among many other things) linking hypnosis and hysteria. He recognized that hysteria had variable manifestations and that hypnotic phenomena could occur in seemingly normal individuals, but he still viewed hypnosis as a kind of artificially induced pathology (his terms included "sommeil nerveux," or nervous sleep; and "un état nerveux artificiel ou expérimental," an artificial or experimental nervous state) which could be used to demonstrate symptoms of hysteria (1). Janet (2) went even further in identifying the two as one phenomenon: "The hypnotic state has never any character which cannot be found in natural hysteric somnambulisms." He added that patients who recovered from hysteria lost their hypnotic capacity, which is unlikely according to current research, but he noted that "subjects troubled with other diseases than hysteria—epileptics, for instance, psychasthenics tormented by the mania of doubt, lunatics affected with systematic delirium—are not at all hypnotizable. . . ," which is an observation quite consistent with our hypothesis.

Breuer and Freud began their classical explorations of the unconscious via hysteria, which they defined in terms of ego disintegration and eruption of the unconscious. In their early explorations they employed hypnosis, largely for purposes of abreaction. Freud later decided to abandon the hypnosis because he thought it distracted from analysis of the transference, which left us with many unanswered questions. Breuer wrote an interesting footnote in his theoretic discussion of hysteria:

> The miraculous workings of hypnosis are, so far as I can see, only observable in hysterical patients. What we should be doing would be first to assign the phenomena of hysteria to hypnosis, and then to assert that hypnosis is the cause of those phenomena." (3, p. 248)

We would agree with this observation and argue that many hysterical signs and symptoms may be related to these patients' profound capacity to be hypnotized, although we would not agree that hypnosis is confined to hysteria or that high hypnotizability implies psychopathology.

Subsequent analytic writers have pointed out more serious character pathology underlying what Freud described as hysterical neurosis (4, 5). In reviewing the psychoanalytic literature, Chodoff (6) noted the importance of situational factors, particularly environmental stress, in eliciting hysterical features. He commented that what commonly passes for hysteria looks more like a male caricature of female traits and defined hysteria as a language of action, emphasizing the interpersonal communicative aspects of hysterical symptoms.

From a statistical diagnostic perspective, some have defined the syndrome in terms of multiple somatic complaints (7), while others have pointed to the relative instability of the diagnosis of hysteria (8). Slater (9) has gone so far as to attack the concept of hysteria as "a delusion and a snare."

The phenomenon of hysterical psychosis per se has been given some attention, largely in the work of Hollender and Hirsch (10, 11). They described a psychosis that may include hallucinations, delusions, depersonalization, and usually volatile affect. They noted that such a psychosis may occur in individuals with characteristics consistent with the diagnosis of hysterical character. These authors emphasized, in particular, extreme sensitivity to cues from other people, emotional volatility, the need to behave in accordance with the expectations of others, a tendency to live for the moment, and an orientation toward "affective truth" (10). In a later paper (11) they clarified this concept by subdividing the syndrome of hysterical psychosis into three different types: 1) "culturally sanctioned behavior," which involves data from anthropologists regarding the acts of madness that perform certain social functions in non-Western societies (12, 13); 2) "the appropriation of psychotic behavior," in which a suggestible individual acts out his or her identification with an important person in his or her life who is psychotic; and 3) "true psychosis," with eruption of unconscious material and modification of ego function relating to the evaluation of reality.

Among others who have written on hysterical psychosis, Siomopoulos (14) described it as a pattern of regressive behavior related to childlike thought activities and the merging of fantasy with reality, but with the patient always conveying some awareness that the delusional material is not entirely believed or taken seriously. In a particularly interesting paper, Mallet and Gold (15) discussed a "pseudo-schizophrenic hysterical syndrome" in women with a history of superficial object relations, multiple somatic complaints, and sexual dysfunction along with a depression characterized by complaints of loneliness and emptiness, dramatic affect, and visual hallucinations. All of these women were eventually diagnosed as hysterical but also received a schizophrenic diagnosis at one time or another during their treatment. Of particular interest is the authors' observation that these patients had great difficulty expressing their plight in words, which is perhaps a factor in their preference for dramatizing their situation in action. This use of action as a language is quite consonant with other descriptions of hysteria (6, 16).

The usefulness of assessing hypnotizability in differential diagnosis was suggested by Spiegel (16) in a clinical report on a number of highly hypnotizable patients who demonstrated in common an intense capacity for affiliation, a proneness to relinquish control in an interpersonal setting, a tendency to live in the present rather than in the past or future, and to rely on feelings rather than thinking in making decisions, a capacity for dramatic affective states, a tendency toward compulsive compliance to the demands of others and, consistent with this, an inner core of self-doubt and sense of worthlessness.

The usefulness of hypnotizability assessments in differential diagnosis has been corroborated by Frankel and Orne (17), who found that phobic patients were more hypnotizable than cigarette smokers on the Stanford Hypnotic Susceptibility Scale (18). Spiegel and his coworkers have demonstrated a statistical relationship between certain patterns of performance on the Hypnotic Induction Profile (19, 20) associated with little or no hypnotizability and the existence of serious psychopathology, including schizophrenia (21). A response on this test consistent with high hypnotizability has been reported to be associated with a vulnerability to neurotic disorders, especially hysteria, among the highly hypnotizable (22). Frankel (23) interpreted the symptoms of two phobic patients with relatively high scores on the Hypnotic Induction Profile as spontaneous trance phenomena.

While some workers maintain that schizophrenics are at least as hypnotizable as the normal population (24), the trend of research in this area within the past 15 years has indicated generally lower hypnotizability and the absence of very high hypnotizability among chronic schizophrenic patients (25–28). These findings are consistent with our clinical experience with the Hypnotic Induction Profile. We have observed that as a group schizophrenic and seriously depressed patients frequently show "decrement" patterns on the test, indicating little or no hypnotizability, while healthier individuals, usually outpatients, obtain higher "intact" scores. Disorders of thought or mood seem to interfere seriously with the kind of concentration measured by this test of hypnotizability. Thus, it seems plausible that measurement of the capacity for

attentive, intense focal concentration with diminished peripheral awareness that is characteristic of the hypnotic state may prove useful in discriminating between a psychosis of hysterical origin and schizophrenia or other more malignant psychiatric disorders.

The literature we have cited on hysterical psychosis has described a particular proneness in these individuals to comply with direct or implied environmental cues. In particular, some hysterical psychoses may be attributable to identification with a psychotic person close to the subject. This proneness to identification is a recognizable part of the syndrome of high hypnotizability (16). There have been several suggestions, notably the contribution of Laing (29), that psychoses in general and schizophrenia in particular are means of communicating with the environment and that so-called psychotic symptoms are really not so insane when understood in terms of the suffering inflicted on an individual by the people around him. This existential approach raises fundamental questions about our assumptions of sanity and madness, but it seems to fly in the face of genetic data, which suggest that there may be an inherited predisposition to schizophrenia (30). It may well be that an existential analysis is most appropriate to those individuals with hysterical psychosis, who seem very sensitive to clues from the environment. Interestingly, the genetic data of Rosenthal and associates (30) point to a distinction between those individuals with chronic and borderline schizophrenia, who seem to have a genetic loading for the disease, and those with acute schizophrenia, who do not.

Our thesis is that the phenomena associated with the syndrome of hysterical psychosis may be simplified and understood best by reference to the profound hypnotic trance states of which such individuals are capable. From this point of view such hysterical symptoms as fugue states, amnesia, and hallucinations are understood as spontaneous, undisciplined trance states. Some individuals, in the face of dramatic stress within their family, at their job, or social pressure of other kinds may succumb to a psychotic form of communication which is different from schizophrenia in phenomenology, course, and prognosis. The following case examples are illustrative.

CASE STUDIES

Case 1. Michael, a 15-year-old boy, was agitated and combative when he was brought to a hospital emergency room. He was placed in four-point restraints. He told the admitting physician that he was "possessed by demons of Satan." Michael reported that when he was lying in bed at home that evening he began to feel "shaky." He was then amnesic for the events that followed until he came to the hospital. His family noted that he began speaking "in a bizarre, awful voice, uttering obscenities, grunting, growling, and sniffing like a wild animal." They became frightened and attempted to hold him down, but he struggled with them. The family reported that he had "superhuman strength" while in this state, and the police were called to help get him to the hospital.

Michael and his twin are the youngest of five siblings in a middle class, religious family. Neither the patient nor anyone in his family had psychiatric history. Three months before his admission, Michael was moved to the bedroom of an older, sexually active sister, who was away at college during the week but returned on the weekends, sometimes with her fiance.

Ten weeks before admission, Michael became involved with his first girlfriend. This relationship lasted only 6 weeks, at which point his girlfriend left him in favor of one of his friends. He felt quite despondent over this, but was unable to verbalize his feeling until a week before his admission, when he took a butcher knife from the family kitchen, walked to his girlfriend's house, and made a superficial laceration on his arm. His girlfriend rushed him to her church, where he was told by a trusted minister that this was Satan's work.

When he was admitted one week later he was well oriented in all spheres and cooperative. He displayed goal-oriented speech, his affect was flattened, but he was noted as being mildly depressed. His memory was intact except for the events that had led to his hospitalization. He had suicidal ideation without intent and without vegetative signs of depression. He denied homicidal intent and did not have gross paranoid thought patterns. He said he had no hallucinations and was free of delusional thinking, with the exception of the thought that he might be "possessed by demons." His proverb interpretation was concrete, religiously oriented, and personalized. He was admitted to the hospital, diagnosed as having psychotic depression, and treated with trifluoperazine in doses of 10–20 mg/day. During his hospitalization, he was quiet and cooperative and did not show evidence of bizarre behavior at any time other than during family visits. The ward staff considered him a paranoid schizophrenic after he received a full medical and endocrine work-up that revealed no abnormality.

A week after admission, Michael was examined using the Hypnotic Induction Profile (HIP). His initial score was 4–5 on the 0–5 scale, and when tested 2 weeks later, his score was 5. He was capable of a profound trance state and was able to regress to the past as though it were the present. When regressed to the time of his initial possession episode, he began to relive it with dramatic affect, screaming and talking in a strange voice about his Satanic possession. The patient was taught to bring on one of these attacks and was told that he should practice bringing them on because he would gradually learn to modify them and they would become milder and milder. He was discharged from the hospital 2 days later. He did well at home at first and was quite proud of his ability to bring on the attacks. His family was counseled not to be frightened of him, to use calm reassurance, and to stroke him on the forehead, a signal which had been used during the hypnotic regression to end his reliving of the possession state.

Michael had a second brief hospitalization. While at home, he began crawling on the ground, barking like a dog, and appeared unable to bring himself out of the state. His mother did not panic and said to him sternly: "I don't care who you are, come to the table and eat your dinner." He concurred, lapping milk out of his glass and refusing to use silverware. Later, he became more excited and was returned to the hospital. He went through an episode of wild screaming and laughter and was instructed to put himself into a trance state and bring himself out of it when he was ready. He came out of this state and became quite coherent and quiet within a few minutes. Several days later, he was discharged from the hospital to be followed in family therapy.

One week after Michael's hospital discharge and 1 month after antipsychotic medication had been instituted, it was discontinued because of sedative side effects and the absence of any evidence that his improvement was related to the medication.

Further interventions were made with the family. Michael was moved to a bedroom of his own and the family was urged to focus less attention on him, particularly for his episodes of possession, and to reinforce other, more desirable behavior. The concordance of Michael's psychosis with his environment is intriguing. The family believes in demonic possession. Michael had been reading a Satanic bible and was quite interested in the occult. The information elicited during family therapy revealed that in many ways Michael was quite resentful of the family's intense emphasis on religion. One interpretation is that Michael's psychosis was his way of sayng, "OK, if you want religion, this is what you will get." This had been a chronic issue with him. The acute pressure that led to the temporary ego fragmentation and eruption of unconscious material seems to have been the combination of his being forced into intimate contact with his older sister and her sexuality and his loss of a first girlfriend. The patient could only view such a situation as demonic and in a sense he was possessed by forces beyond his control. His illness succeeded in getting him out of the oversexualized family situation in the short term and then getting him out of his sister's room in the long run.

What is particularly striking about this case is the patient's rapid and dramatic decompensation, his psychotic symptoms, and the rapid recompensation, which was apparently unrelated to the use of neuroleptics. The patient was clearly responding to intense family pressures, and he proved repeatedly to be highly hypnotizable. Although he was psychotic and delusional, his affect was atypical in that he was capable of forming good rapport in the intervals between his states of possession, and he showed periods of intense and dramatic affect. However, he was delusional and his thinking could easily be described as autistic, at least in certain areas.

At 1-year follow-up, Michael is doing well without medication or therapy.

Case 2. Ms. A, a 31-year-old separated working mother of four, first came to our attention after she was admitted to the hospital following a suicide gesture, the ingestion of a small number of aspirins. This action was precipitated by a sexual advance from a man she had recently met. She was a well-groomed woman who displayed exaggerated affect while giving an excessively detailed and dramatic history. She was oriented in all spheres, her memory was intact, and she was judged to be of above average intelligence. She was felt to be engaging and seductive.

Ms. A showed no evidence of delusional thinking and her associations were not loosened. She did, however, admit to both auditory and visual hallucinations, which took several forms. She reported being able to "see through people," i.e., she saw visual representations of her feelings about them. For example, she reported seeing flames burning inside of certain men. Ms. A also reported that before she married her husband she visualized and spoke with her husband's deceased father about the advisability of marrying his son. More recently, she said that when she was driving alone in her car, another woman would appear and the two of them would discuss whatever was bothering Ms. A. The imagined woman was noted to be much different from Ms. A in voice, appearance, and self-confidence. Ms. A also had a long history of numerous complaints such as headaches, low back pain, allergies, and "hypoglycemia," with no apparent organic basis.

The Hypnotic Induction Profile showed Ms. A to be highly hypnotizable (3–4 on the 0–5 scale). Individual psychotherapy was begun and no medications were prescribed. The patient was hospitalized for 2 weeks and discharged without medication to be seen weekly for psychotherapy.

The focal point in therapy was Ms. A's difficulty entrusting herself with any real independence. She had been prone to allow others to make decisions for her, although she became increasingly unhappy over this situation in her marriage. Her ambivalence over the sexual advances she received after her separation from her husband led to situations wherein consciously unwanted sexual involvement was expected of her. Her desire to please and her mistrust of her own judgment made this pattern very difficult and anxiety-provoking, and in this context she developed hallucinations and suicidal ideation. She was helped to see that her desire to please and her self-doubt were part of her character style and in certain interpersonal situations could be understood as spontaneous trance states. By learning to control her entry into and exit from the trance state, Ms. A was then able to control her anxiety about making decisions without resorting to hallucinations and suicide gestures as defenses. Hypnotic regression was used to help the patient relive stressful experiences and her reactions to them. As she reexperienced the anxiety and hallucinations, she was taught how to think through alternative responses and make choices independent of the desires of people around her.

When therapy terminated 5 months later, Ms. A had decided to divorce her husband, had moved out on her own, and had gained steady employment. She was also enjoying an active social and sexual life.

In this case, the use of hypnosis was primarily diagnostic. The patient had psychotic symptoms but was not treated as schizophrenic or psychotically depressed. Her high hypnotizability (a repeat HIP score 2 months later was 4–5) as well as her full affect, her well-groomed appearance, her long marital history, and the lack of positive psychiatric family history all led us away from the more malignant diagnoses. With this perspective, her symptoms were seen as nonverbal communications—she hallucinated flames inside men rather than discussing their sexual advances or more directly understanding and confronting her own sexual wishes. She was helped to structure her world so that she would have more control over her involvements and would value her own judgment and wishes more highly.

DISCUSSION

The two individuals we have described share several characteristics: relatively young age, a history of good premorbid adjustment, a rapid and florid decompensation related to environmental stress, and high hypnotizability. In each case, there was a dramatic symbolic content to the psychotic symptom. Michael was possessed symbolically by the devil but actually by the intense incestuous wishes that his living situation accentuated. Ms. A hallucinated flames inside of men, which represented sexual arousal. The psychotic symptoms can be understood in Chodoff's sense (16) as a means of nonverbal communication about the individual's plight.

Hypnosis was used as part of the differential diagno-

sis and also in the course of treatment. Each of these subjects was found to be highly hypnotizable, on the Hypnotic Induction Profile, and this trance capacity was used to demonstrate to the patients their ability to bring on their own symptoms and thereby to master them. Such patients are often extremely sensitive to environmental cues. It was necessary to remove Michael from the sexual stimulation within the family in order to maintain lasting control over his symptoms. Ms. A was taught to see her symptoms in a new light as a dramatic means of expressing a conflict over her change in marital status and sexual experience.

Because these individuals are so compliant, they can easily slip into a pattern of chronic psychological dysfunction if that is the expectation of their therapist and treatment environment. Thus, it is particularly important to identify such patients early. In these cases, even in the absence of the test of hypnotizability a poor response to antipsychotic medication, as in Michael's case, should suggest the possibility of alternative diagnoses to schizophrenia. Such individuals fall into the group of psychotic patients who are considered to have the best prognosis, with good premorbid adjustment, severe environmental stress, rapid decompensation, and relatively rapid recompensation. It is possible that the assessment of hypnotizability will be of significant usefulness in selecting those psychotic patients who will respond to individual and family psychotherapy and who are not in need of antipsychotic medication. Statistical research on the subject with a much larger number of patients is planned.

Research and Development of Naltrexone: A New Narcotic Antagonist

BY DEMETRIOS A. JULIUS, M.D.

The author reviews the history of federally supported research in the field of narcotic antagonist therapy, focusing on social, political, and governmental issues. He describes the criteria for establishing an optimum narcotic antagonist, the legal guidelines for drug development, and the currently available narcotic antagonists. Research supported by the National Institute on Drug Abuse has indicated that naltrexone is the most promising drug in this category. The author discusses the safety and clinic use of naltrexone, the status of the NIDA naltrexone program, and plans for future development of the drug.

THE CURRENT naltrexone research program supported by the National Institute on Drug Abuse can be traced developmentally to its embryonic beginnings in the mid-1960s. At that time, Martin and co-workers (1) at the Addiction Research Center in Lexington, Ky., initiated a series of studies on the use of narcotic antagonists to treat opiate dependence. The studies were a practical outgrowth of the theoretical formulations elaborated by Wikler (2, 3) over the preceding years. The studies showed that a narcotic antagonist could effectively block the euphorigenic and dependence-producing properties of opiates in man. Furthermore, the antagonist produced neither physical dependence nor abuse potential. This was important because previous treatment drugs had the liability of producing their own degree of addiction.

These early clinical studies of narcotic antagonists might have faded into textbook obscurity had it not been for a number of concurrent social and political events. During the 1960s, experimental and compulsive drug use became widespread. All manner of substances appeared on the street market, and many individuals sought refuge in the blissful escape they supposedly provided. For many, one dead-end to which these pharmacologic avenues led was heroin addiction. Consequently, by 1970 the use of heroin, both at home and among our military personnel abroad, had reached alarming proportions. This situation provided the necessary impetus to both the executive and legislative branches of the government to authorize funding for expanded research on and treatment of opiate dependence.

On June 17, 1971, President Nixon signed a bill authorizing the creation of the Special Action Office for Drug Abuse Prevention (SAODAP) to coordinate the various resources of the federal government to check the continuing spread of illicit drug abuse. These resources previously had been scattered across more than 14 different agencies. In 1972 the Congress passed the Drug Abuse Office and Treatment Act, which was signed on March 21 (P.L. 92-255, section 224). Among the numerous provisions of the law was substantial financial support for the expansion of research on "long-lasting, nonaddictive, blocking, and antagonist drugs or other pharmacological substances for the treatment of heroin addiction." With these substantial mandates, SAODAP's first director, Dr. Jerome Jaffee, set the development of a safe and effective narcotic antagonist as one of the highest priorities of the new office.

THEORETICAL BASIS OF NARCOTIC ANTAGONIST THERAPY

Pharmacologically, a narcotic antagonist is a substance that has the ability to block the euphorigenic and dependence-producing properties of opiates (4). It is currently theorized that the antagonist accomplishes this feat by virtue of its structural similarity to narcotics. Thus, antagonists can occupy the same opiate receptor sites in the body as narcotics, thereby producing competitive inhibition of narcotics. Different narcotic antagonists also have differential abilities to produce both antagonistic and agonistic action. These differential properties are, of course, important in choosing the proper narcotic antagonist for therapeutic use. It should be noted that a pure narcotic antagonist differs greatly from a drug such as disulfiram. When alcohol is ingested by an individual who is taking disulfiram he or she then experiences a violent physical reaction that can be life-threatening. When heroin is injected in a dose that is completely blocked by the dose of a narcotic antagonist, there is no phys-

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977. Received May 20, 1977; revised May 25, 1978; accepted Aug. 7, 1978.

When this paper was written, Dr. Julius was Administrative and Research Psychiatrist, National Institute on Drug Abuse. He is now Director, Social Development Center of Tehran. Address reprint requests to James Julius, M.D., General Delivery, APO New York, 09233.

ical reaction. Of course, an individual may attempt to overcome the blockade by using too much heroin, which can lead to a fatal overdose.

This unique class of antagonist drugs thus formed the basis of a potential treatment modality as outlined by Wikler (2, 3) and Martin and associates (1). These researchers postulated that operant conditioning plays an important role in initiating and perpetuating heroin use. Initially, the euphorigenic properties of narcotics probably act as strong reinforcers of what is conceptualized as "drug-seeking behavior" in the opiate-dependent individual. Thereafter, tolerance to the narcotic develops and slowly reduces the euphoric effects. In addition to the pursuit of pleasure (the euphoric effects), there is now within the individual a growing awareness of the need to avoid pain (the abstinence syndrome). This avoidance of the discomforts of abstinence also perpetuates the drug-seeking behavior. Finally, a hypothesized "conditioned abstinence syndrome" apparently can be precipitated by environmental stimuli that have been associated with opiate dependence in the past. Occasionally, dependent individuals have described the onset of withdrawal symptoms after opiate detoxification as a result of merely coming into contact with their previous environment. This conditioned abstinence syndrome may be characterized by increased reactivity to stimuli, prolonged abnormal autonomic responses, feelings of dysphoria, and often an intense "craving."

It was quite logical to conclude that the narcotic antagonist could be used to control these various determinants of opiate-seeking behavior. Since the antagonist would block not only the euphoria but also the physical dependence produced by opiates, reinforcement of conditioned abstinence through reestablishment of unconditioned physical dependence would be eliminated and gradual extinction of the response would occur. Eventual extinction of opiate-seeking behavior would be the expected consequence of blockade of the two primary reinforcing properties of opiates, namely, production of euphoria and suppression of the opiate abstinence syndrome, both unconditioned and conditioned.

The protection afforded by the antagonist would provide the needed time to aid the detoxified individual in altering his life course. In a close and humane psychotherapeutic milieu, the individual could then learn to regain control over his own destiny. He could begin to develop greater internal controls and greater independence and to extricate himself from the external web of drugs and environmental pressures that had previously ruled his life.

THE DEVELOPMENT OF AN OPTIMUM NARCOTIC ANTAGONIST

In light of the sociopolitical milieu and the enticing theoretical notions about the antagonists, we can easily understand why the development of a safe, effective antagonist was of the highest priority for SAODAP in 1971. SAODAP directors also recognized that the selection and development of such an antagonist was of no burning interest to the pharmaceutical industry. The projected expenditure of research and development funds and time seemed to outweigh the projected returns from what appeared to be a limited market.

By law, any new drug must pass through rigorous and controlled testing in several animal species as well as in humans before it can be marketed. The testing is divided into a preclinical phase and three clinical phases. In the preclinical phase, the gamut of toxicity studies should be carried out on at least two different animal species. If the drug proves to have a sufficient margin of safety in these toxicity studies, it may then be introduced into man for the purpose of gathering safety and efficacy data. Phase 1 of the clinical studies deals with the basic clinical pharmacology of the drug in man. This covers such areas as dosage levels, absorption rates, and metabolites. Phase 2 represents limited and quite controlled clinical trials intended to demonstrate the safety and relative efficacy of the drug. For reliable results, it is desirable that these studies be carried out within a double-blind placebo design. Phase 3 represents both controlled and uncontrolled clinical investigation in a much larger group of patients. The successful completion of this phase and the demonstration of drug efficacy is the final step before a new drug application (NDA) is submitted to the Food and Drug Administration (FDA). With approval of the NDA, the drug then is eligible for marketing. Of course, there is a constant financial risk involved in this process because development may be halted at any point on the basis of unacceptable toxicity or lack of efficacy.

It was with this long and complex procedure ahead that the federal government, through SAODAP and the Division of Narcotic Addiction and Drug Abuse (DNADA), undertook the development of a safe, effective narcotic antagonist. A research plan was initiated by DNADA in September 1971 to help organize such an efficient development. In this plan were outlined the necessary preclinical research, the procedures for clinical testing, and the cost and personnel estimates. In addition, the optimum characteristics of narcotic antagonists were described as follows:

1. Ability to antagonize the euphoric effects of opiates.
2. Absent or minimal agonistic effects, especially unpleasant ones.
3. Not physically addicting.
4. No increasing tolerance to its antagonistic actions.
5. Absence of serious side effects and toxicity even in chronic use.
6. Ease of administration, i.e., no surgery or painful procedure involved.
7. Long-lasting or moderate duration of antagonist effects.

783

8. Absent or low abuse potential.
9. Reversible effects in case of medical emergency.
10. High potency, to allow administration of small amounts in a biodegradable vehicle.
11. Ease of availability and reasonable cost.
12. Therapeutic efficacy in the treatment of narcotic addiction.

By early 1972 there existed several antagonists at various stages of development, the purest of which was naloxone. Naloxone, which had been available as a narcotic antagonist for many years, seemed to be a potent antagonist and at that time showed almost no agonist action. Its main drawbacks as a therapeutic agent in opiate dependence were its high cost, the difficulty in synthesizing it, its very poor oral absorption rate, and, particularly, its short duration of action in the body. Naloxone had been approved by the FDA for short-term use in humans as an antidote for opiate overdose. In spite of its drawbacks, naloxone had met with limited success as an adjunct to treatment. This seemed encouraging for narcotic antagonist treatment in general.

Concurrently, another promising and potent antagonist, cyclazocine (5–7), was being developed. This drug demonstrated a longer duration of action (up to 24 hours with a 4-mg dose). However, cyclazocine had drawbacks—strong agonist properties including psychotomimetic effects and quite unpleasant feelings described as dysphoria. Despite the tolerance that develops to these effects, cyclazocine was not well received by the addict volunteers and soon acquired a bad street reputation. However, cyclazocine was successful in the treatment of some individuals, and the drug is still being used in certain clinics in New York City.

Three other compounds, designated as M-5050, BC-2605, and EN-1639A, were in the early stages of animal and human testing at this time. One of these, EN-1639A, seemed to be a potent antagonist and did not show the dysphoric and unpleasant side effects of cyclazocine (8). The drug, which came to be known as naltrexone, had a good duration: 50 mg seemed able to block narcotic action for 24 hours. By late 1972, there was a substantial supply of the drug available for testing. By mid-1973 it became evident that naltrexone fulfilled the criteria for an optimum narcotic antagonist to a greater degree than any of the other available substances (9–13).

In addition to the research progress that was being made, there were also administrative changes occurring within the government. In 1973, the Division on Narcotic Addiction and Drug Abuse was separated from NIMH and expanded into the National Institute on Drug Abuse (NIDA). Thus, from 1973 to 1974, NIDA and SAODAP shared the responsibility for the development of the narcotic antagonists in general and of naltrexone in particular. By mid-1974, as SAODAP was being phased out of existence, the entire direction and monitoring of the naltrexone research program fell to the NIDA Division of Research.

NIDA-SUPPORTED NALTREXONE RESEARCH

From 1973 to 1974, NIDA supported 26 grants and contracts in preclinical and clinical studies directly related to narcotic antagonists. This support totaled over $5 million. Approximately 17 of these grants and contracts dealt with the use of naltrexone in clinical situations, and they fit together into a rather loosely knit naltrexone research program. Five of these research clinics were selected to participate in the double-blind placebo study of naltrexone that was being conducted by the National Academy of Science (NAS). It was planned that such a study would satisfy in an elegant manner the phase 2 requirements for new drug development and would demonstrate the safety and relative efficacy of naltrexone when compared to placebo. The five NAS clinics in the double-blind study followed a standardized group of three research protocols. Each protocol involved subjects with a different type of opiate dependence. The Baltimore and New Haven clinics used only "postaddicts" in their research, the Detroit and Sepulveda clinics used only methadone maintenance addicts, and the St. Louis clinic used only "street addicts."

By contrast, the remainder of the grants and contracts consisted of a variety of controlled and uncontrolled clinical trials with naltrexone (14–20). Researchers in this group were free to use different protocols, different treatment settings, different types of dependent subjects, and different research questions. This group of grants and contracts was called "NIDA clinics," for want of a better title. These NIDA clinics were later divided into a group of "open clinical naltrexone studies" and a group of "behavioral naltrexone studies" in an effort to bring greater order and specificity to the overall naltrexone program. The former category consisted of studies that tested naltrexone within a variety of clinical contexts, and the latter category consisted of those which specifically attempted to test the original behavioral formulations discussed above.

All of these studies underway by 1974 were thought by NIDA to represent phase 2 testing, i.e., naltrexone was receiving exposure in limited clinical populations. In phase 2, one of the chief responsibilities of NIDA was to provide a watchful eye over the safety aspects of this drug when it was administered to humans. Consequently, a tight monitoring system had to be devised if the limited staff at NIDA was to function properly in detecting any ill effects of the drug. It was therefore decided to establish the same kind of monitoring for the NIDA research clinics that was in use at the five clinics in the NAS study. Biometric Research Institute (BRI) of Washington, D.C., was providing the monitoring and statistical capabilities for the NAS study and had developed a number of forms in conjunction with the NAS Committee on Evaluation of Narcotic Antagonists to carry this out. NIDA therefore contracted with BRI to provide a similar monitoring function for the NIDA clinics. This consisted of gathering

information on the monthly laboratory records, monthly physical and psychiatric summaries, weekly symptom checklists, and the daily treatment records from the various open clinical and behavioral NIDA studies. Thus, by early 1975, NIDA was able to gather a large quantity of both safety and efficacy information into the central data bank of BRI and to keep constant and close watch over any potentially unpleasant or harmful effects of the drug.

Up to the time this paper was written, no dysphoria or other undesirable psychic effects from naltrexone had been reported. The question had arisen in the past whether naltrexone caused an increase in blood pressure. According to the collective data, there seems to be a small (2–3 mm Hg) but not statistically significant rise in both systolic and diastolic pressure after the initial administration of naltrexone. However, by four to six weeks, blood pressure returns to baseline, and in many cases both systolic and diastolic pressure decreases by 2–3 mm Hg (reference 21 and personal communication from R. Resnick, December 1975). The only occasional side effect seems to be abdominal and gastrointestinal discomfort in some subjects. When this was found during the early stages of treatment, it was attributed to minor withdrawal symptoms because opiates were presumably still in the addict's system. However, these symptoms also have been reported later in treatment. Some researchers have found that these symptoms are in some cases relieved by antacids or by administering naltrexone to the addict after he has eaten. Thus, naltrexone may be a gastric irritant for some addicts.

However, to date there have been established no serious lasting side effects directly attributable to naltrexone. This antagonist appears to be a rather safe chemotherapeutic agent for the treatment of opioid dependence.

It is intriguing to consider what interaction naltrexone may have with the endogenous opiate-like compounds that have recently been isolated (22–24). Could the abdominal symptoms be related to such an interaction? If an individual who is being maintained on naltrexone has a quantity of this endogenous substance secreted into his system and it is, in fact, opioid in nature, is it not possible that some physical effects will be observed? This symptomatology might include minor withdrawal-like symptoms characterized by the abdominal discomfort described above. However, another explanation might be that naltrexone has some agonistic properties. Recent animal data, for example, document that even naloxone, thought to be a "pure" narcotic antagonist, has agonistic properties.

THE NALTREXONE PROGRAM: PRESENT AND FUTURE

Phase 2 of naltrexone testing has officially ended. The final reports from the CENA committee on the NAS study and from BRI on the NIDA studies, which were due in May of 1977, were submitted to the FDA for final approval to proceed to phase 3 testing. They have not been published as yet in the public sector. By the publication date of this paper, phase 3 of naltrexone testing should be well on the way to completion.

The preliminary data analysis certainly underscores the safety of naltrexone and also points to some measure of therapeutic efficacy. In the NAS study, 192 subjects received at least one dose of study medication—94 on naltrexone and 98 on placebo. The number of dropouts throughout the nine-month double-blind study was, of course, quite large—larger than expected. Nevertheless, at the end of nine months, approximately 7% of the subjects remained. During the middle months of the study (from $2^1/_2$ to $5^1/_2$ months), there appeared to have been a substantial difference in retention between the naltrexone group and the placebo group.

In addition to the NAS study, about 1,005 individuals have taken at least one dose of naltrexone in the other NIDA-sponsored clinics. The resultant retention curve of all these clinics combined is very similar to that seen in the NAS study. The final nine-month retention figure of 5% is somewhat lower than in the NAS study.

It seems that naltrexone is of long-term benefit to only a small percentage of addicted individuals. However, this small percentage represents quite a large population when one considers the total number of addicts in the United States. What may prove to be of greater therapeutic interest is naltrexone's 60% and 40% retention rates at one and two months. This fact may lead us to rethink the best way to use naltrexone in a treatment setting. In addition to long-term chemotherapeutic maintenance, we may begin to use it in conjunction with short-term crisis intervention or with behavioral techniques. Furthermore, naltrexone might successfully be used in a preventive contingency manner, i.e., the addict could ask to be put on the drug when he felt the need arise. Other factors that may be crucial to drug efficacy and that deserve further research include attitudinal, environmental, and sociocultural variables in the clinic personnel and in the addicts treated. In other words, is there a subgroup of addicts that can be described by these variables, as well as by personality variables, who would be candidates for naltrexone therapy?

Some of these questions hopefully will be addressed in phase 3 of the research. The possibility is being explored that Endo Laboratories, the pharmaceutical company which holds the patent on naltrexone, will take over the phase 3 development task. NIDA would like to have that phase begin soon so that naltrexone can reach the marketing stage as quickly as possible. As sentiment mounts against other dependence-producing agents such as methadone, we may well be turning to a therapeutic program that includes naltrexone as a pivotal component. It is NIDA's hope, therefore, that further research will continue to expand naltrexone's efficacy and will establish the place

of naltrexone therapy within the overall treatment approach to opiate dependence.

Emergency Room Medical Clearance: An Educational Problem

BY MICHAEL P. WEISSBERG, M.D.

The term "medically clear" has a greater capacity to mislead than to inform correctly. The overuse of this term, especially in emergency room settings, may indicate difficulties in medical education and in the consultation/referral process between psychiatry and other specialties; further, it results in poor patient care. Nonpsychiatric physicians may prematurely refer patients as medically clear because of their unfamiliarity or discomfort with clinical psychiatry. Psychiatrists often ask for medical clearance of patients to hide their discomfort with or antipathy toward clinical medicine. The use of emergency room settings for interspecialty collaboration and training helps minimize the underlying difficulties that lead to the use of this term by fostering psychiatric skills in nonpsychiatrists and a sense of medical identity in psychiatrists.

THE USE of the label "medically clear" in emergency room settings hinders patient care by impeding the flow of information between psychiatric and nonpsychiatric personnel. The imprecision and varying meanings and uses of medical clearance are symptomatic of problems in medical education. At times, the medically clear label reflects and is used to obscure psychiatry's discomfort with medical problems and medicine's discomfort with psychiatry. The purpose of this paper is to examine some of the meanings and uses of medical clearance and to suggest some solutions for the educational problems that underlie this phenomenon.

The emergency room is an ideal but often neglected educational setting. Few settings are as appropriate for learning about interdisciplinary collaboration. However, when emergency room duty is treated by training programs as nothing more than a service obligation, residents and interns may invest themselves minimally. Their work may become sloppy and patients may be "disposed of" with inadequate diagnosis and treatment. In this sort of atmosphere medical clearance is a common reason for referrals of patients to the psychiatry service.

The term "medically clear" sounds legitimate and precise, especially to the inexperienced clinician. However, a thorough search of the literature revealed no information on the origins of the term. The label is applied in at least three situations when patients are referred to the psychiatric service.

1. It is thought that there is no medical illness present. An illustrative case is described below.

Case 1. A 26-year-old teacher complained of anxiety and spells of confusion. She was in the midst of divorce proceedings and had been disowned by her family because she was living with a man they considered beneath her. She had had two previous psychiatric contacts. The patient was medically cleared, diagnosed as having anxiety attacks, and referred for further psychiatric care. On closer examination, she also related some visual difficulties and problems with speaking and calculation. She was subsequently diagnosed as having had a stroke from which she later recovered.

2. A medical illness is known to be present but is not thought to be the primary cause of the patient's symptoms, as is shown in the following case.

Case 2. A 56-year-old woman with a history of chronic alcoholic liver disease was brought to the medical emergency room by relatives because she had become increasingly agitated since the sudden death of her husband 2 days before. The previous night the patient had misidentified her brother as her dead husband and had defecated in a trash can. She was medically cleared and referred to the psychiatry service with a diagnosis of acute grief reaction. The patient had a difficult time attending to the interview; she was intermittently agitated, disoriented to time, and unable to remember more than one object out of three after 5 minutes. The psychiatrist ordered a urinalysis because he noted slight scleral icterus. The urine contained bilirubin. After the patient was admitted to the medical service she was diagnosed as having fulminant viral hepatitis superimposed on chronic alcoholic liver disease. The patient's organic brain syndrome was making it impossible for her to grieve.

3. It is thought that the medical illness that was present no longer needs medical treatment, as illustrated below.

Case 3. A 26-year-old single unemployed man was admitted to the emergency room after he took an unknown quantity of pills because of an argument with his girlfriend. He was given gastric lavage and after an unsuccessful attempt to identify the medication was referred to the psychiatry service as medically clear. The patient was somewhat somnolent

Received Aug. 30, 1977; revised Jan. 26, 1978; accepted March 29, 1978.

Dr. Weissberg is Associate Professor of Psychiatry and Director, Emergency Psychiatric Service and Clinical Affairs, Colorado Psychiatric Hospital, University of Colorado School of Medicine, 4200 East Ninth Ave., Box C 261, Denver, Colo. 80262.

but could speak coherently. Although he was oriented, he had a slight defect in memory. His pupils were dilated and his pulse rate was elevated. The psychiatrist felt the patient was suffering from an anticholinergic syndrome and should be given cardiac monitoring in case he had arrhythmias. The medical resident agreed only after the pills were identified as amitriptyline.

Misdiagnosis and premature referral may occur with or without the patient being labeled medically clear, but the term does have an authoritative ring and implies exhaustive study. However, it does not convey what conditions were considered and how they were ruled out; it implies that everything was done and nothing was found. Thus, this designation can offer false assurance to the next professional who sees the patient and thus impedes the evaluation of the patient. The psychiatrist may too often be willing to accept his colleague's authoritative pronouncement rather than exposing himself to criticism, perhaps because he feels his medical skills are rusty.

WHY MEDICAL CLEARANCE?

If the medical clearance label is imprecise, why is it used by medical services and so frequently asked for by the psychiatry service? Perhaps it indicates discomfort in the relationship between medicine and psychiatry and each specialty's ignorance—usually feigned—of the other's field. These factors may result from a deficiency in medical education and a poor sense of medical identity in psychiatry.

Medicine's Contribution to Medical Clearance

Little attention is paid to the consultation and referral process in undergraduate and graduate medical education: some major medical textbooks (1) do not even mention it.

A physician's feelings of intolerance, frustration, or decreased self-esteem can interfere with patient care. If the physician feels that his competence is threatened he may minimize physical findings and tell the patient that his or her problems are "all in your head" (2). In the emergency room, the physician who becomes frustrated with a patient may refer him or her prematurely as medically clear. Further, there is an all too common belief that alcoholics, drug abusers, and suicidal individuals create their own diseases and are therefore less entitled than others to sympathetic and thorough care.

The nonpsychiatrist's unfamiliarity (and in some cases discomfort) with clinical psychiatry also promotes imprecise thinking in this area. For example, a patient with a preexisting psychiatric diagnosis is likely to be referred prematurely (e.g., case 1). Also, many physicians have difficulty conducting or interpreting the mental status examination (e.g., cases 1-3) and distinguishing between functional and organic causes for alterations in mood, thinking, or behavior (3). Even though many physical conditions influence thinking, mood, and behavior, a patient who "acts funny," is frightening, or is frustrating may be referred prematurely as medically clear (4).

Psychiatry's Contribution to Medical Clearance

Some psychiatric residents are uncertain about their status and competence as physicians, and others seem to believe they must "unlearn" medicine to become psychiatrists (5). At times they seem to feign ignorance when it comes to medical matters. Frequently a beginning resident discussing a patient who has been medically cleared ignores such elementary findings as vital signs and does not read thoroughly the medical workup, something that would never have occurred on medical rounds just a few months earlier. This active denial of medical expertise seems to be supported by Greden and Casariego's finding that 42% of psychiatric residents felt that they were psychotherapists first and physicians second (6). Only 39% of the residents in that study said they would do a physical examination of patients they planned to treat psychiatrically. These beliefs were either present before the residency began or developed soon afterward.

Psychiatrists' overvaluation of the medical opinions of other physicians seems to lead them to suspend their own clinical judgment, as is illustrated in the following case.

Case 4. A middle-aged alcoholic man came to the emergency room complaining of restlessness and anxiety. He was medically cleared as showing no evidence of severe alcohol withdrawal, despite an elevated temperature and pulse. However, within a few minutes of his admission by a psychiatric resident he showed rapidly increasing agitation. In a few minutes the patient was grossly delirious.

When this case was reviewed on psychiatric rounds the next morning, the psychiatric resident said he did not feel competent to question the medical clearance, although he had recently had excellent training in a city hospital emergency room as part of his internship. Because of his sense of medical inferiority, he ignored the ominous signs of elevated pulse, temperature, and a rapidly deteriorating course. He forgot that the consultant has the opportunity to make the last mistake.

Others have observed this tendency to repudiate medical identity by some psychiatrists in training. At the same time, older and presumably wiser heads question whether psychiatry should view itself as a medical specialty (7-9). Psychiatry's move away from medicine has been especially prominent in the community mental health field (5). Why does this distancing occur? For some residents it is a result of an original antipathy toward medicine, a problem that was unfortunately compounded for several years by the discontinuation of the internship requirement. Many psychiatric residency training programs seem to have ignored this problem. Gurel (10) reported that only 43% of the residency programs he polled offered interdisciplinary collaboration with medical colleagues, and that collaboration was very rudimentary. There was no mention of collaboration in emergency room work. Further-

more, some supervisors of psychiatric residents do not feel that it is their responsibility to consider, let alone to teach about, the medical problems of patients their residents see. Some supervisors probably screen out of their own practices patients with such problems and hence are unfamiliar with, and presumably uninterested in, medical matters.

Organization of Services and Medical Clearance

Physical separation of clinical areas decreases the possibility of cooperation and collaboration between psychiatric and nonpsychiatric colleagues. Emergency psychiatric services may be located far from the general emergency room, which further promotes an "either/or" diagnostic evaluation of patients. Many psychiatric and medical emergency services are staffed by overworked and inexperienced physicians who may quickly retreat to defensive postures when dealing with other services or difficult patients (11) and are more likely to hide behind the medically clear label.

SOLUTIONS

Problems in the consultation/referral process as exemplified by the medically clear label can be divided roughly into educational, organizational, and attitudinal shortcomings. However, if attention is paid to educational and organizational problems, changes in attitudes tend to follow.

Departments of graduate medical education should realize that the emergency room provides an ideal setting for interspecialty collaboration and training. The emergency room activity of each specialty should be integrated with that specialty's educational program rather than being regarded as a necessary and annoying service obligation. We have found that the institution of evening and weekend teaching rounds, in which the vast majority of senior psychiatric faculty are voluntary participants, has gone a long way toward integrating the emergency psychiatric service into the rest of the department. A full teaching program in emergency psychiatry (weekly supervision and conferences, daily work rounds) fully exploits the educational resources of the emergency room and leads to its being regarded as an important part of the residency training program. Residents feel supported and their efforts pay off in enhanced learning. An added benefit is that psychiatric faculty members have a regular opportunity to hone their diagnostic skills in a medical environment.

Some problems in the consultation/referral process may result from a shaky medical identity, and this factor should be considered in the selection of psychiatric residents. Efforts should be made to screen out applicants who are escaping from medicine and to encourage those who see psychiatry as a medical specialty. Supervisors of psychiatric residents should be alert to the active denial of medical expertise seen in beginning trainees.

Supervisors may also help residents by encouraging them to examine patients and to think through diagnostic possibilities before asking for consultation. This does not imply that the trainee (or faculty member) must stay current with the literature of all major specialties, but he should feel comfortable touching patients, examining them, and integrating his findings into an understanding of his patient's total difficulties.

Patients are also less likely to be "dumped" as medically clear if trainees witness cooperation and mutual respect among staff of different specialties. We have found that the morbidity/mortality conference, which members of many specialties attend, is an ideal vehicle for exploration of the consultation/referral process and for open discussions of difficult cases. Informational matters, such as the diagnosis and management of organic brain syndromes, depression, suicide, grief, hypochondriasis, etc., are presented at weekly seminars by psychiatric staff to nonpsychiatric house officers, medical students, and emergency room personnel.

Physical integration of services also reduces the potential for erroneous "either/or" diagnoses and the use of medical clearance. In order to foster further collaboration and to minimize areas of potential friction between specialties, the department of psychiatry in our facility has created a four-bed combined medical-psychiatric observation and short-term treatment unit in the emergency room. This integrated facility has made it unnecessary, for example, to decide precisely when an overdose patient becomes the responsibility of the psychiatric service.

CONCLUSIONS

The overuse of the term "medically clear" may indicate shortcomings in medical education and in the organization of emergency services. The consultation and referral process is a complex and often delicate form of interprofessional communication. Use of a shorthand phrase raises opportunities for misdiagnosis, premature referral, and misunderstanding. These mishaps can be minimized, and trainees' educational experience enriched, if directors of training programs pay attention to the educational and organizational factors that encourage the inappropriate and/or automatic use of the term "medically clear."

Incidence of a History of Incest Among 18 Female Psychiatric Patients

BY ALVIN A ROSENFELD, M.D.

The author ascertained the frequency of reports of a history of incest among the 18 female psychiatric outpatients he first evaluated or treated in a one-year period. Six of these patients (33%) reported a history of incest. The author suggests that if this figure reflects actual prevalence, previous estimates of a history of incest among female psychiatric patients may have been mistakenly low. He discusses the implications and limitations of the statistics.

IN 1955 WEINBERG (1) stated that the official estimate of the incidence of incest was approximately one case per million population. Many professionals realized that this figure was low because it referred to cases reported to the court, but few expected a significantly higher prevalence. However, since 1955 many authors have been surprised to find a large number of cases of incest among female psychiatric patients. For instance, Lukianowicz (2) discovered that about 4% of all of the female psychiatric patients seen in County Antrim, Ireland, reported a history of incest. Browning and Boatman (3) found that 3.8% of all new cases seen at a child psychiatry clinic in Oregon had a history of incest; all but 1 were females. Similar observations have been made in psychiatric centers in other geographic locations (4, 5).

Studies of women with severely deviant social behavior have yielded even higher frequencies of a history of incest. For instance, among a population of delinquent adolescent girls confined to a state training school, 15% reported having had sexual relations with their fathers or stepfathers (6). Early in this century, a study found that 51 of 103 women arrested by the Chicago vice squad reported that their first sexual experience occurred with their fathers (7). As my associates and I have mentioned (5), it is difficult to assess to what extent the reports of incest among women with a history of socially deviant behavior are influenced by the complex motivational issues involved in the retrospective confession of a traumatic history to authority figures. Nonetheless, incest clearly occurs far more often than previously believed; yet many clinicians continue to consider incest a rare phenomenon.

Most studies of incest have derived incidence figures by adding up the numbers of spontaneous patient reports. To expect that this is an accurate incidence would be to assume that incest is usually reported when it occurs. Few experts believe this. However, most clinicians fear that direct questioning regarding a history of incest might elicit false or fabricated reports from suggestible and compliant patients who sense the therapist's interest. Although this possibility exists, Shengold (8) has noted that patients who have an actual history of incest "wish . . . very strongly that their memories could be regarded as fantasies" and may alter or withhold their history. A clinician who regards a patient's incestuous memories as fantasy may communicate this attitude to a compliant patient, who will then attempt to go along with the therapist's assumption and not report the incest.

In the present study I will describe the frequency of reports of a history of incestuous involvement among all of the female psychiatric patients I have seen in private practice in a one-year period. During this period I used a combination of active alertness to the possibility of incest and more direct questioning. I minimized suggestion to the best of my ability. In this study incest is defined as overt sexual activity involving genital contact between people too closely related to marry. Cases of genital contact for other reasons, such as hygiene, are excluded. Authors who use the term "incest" only when coitus is involved might not consider some of the cases that I would include as incest (e.g., cases of genital fondling). However, I feel that the definition of incest as coitus only is too limited. My associates and I (5) have discussed this issue.

SUBJECTS

Eighteen of the 21 female psychiatric patients I evaluated in a large group and private practice during 1976

Received Oct. 28, 1977; accepted Feb. 10, 1978; revised May 22, 1978.

are included in this study. Three of my female patients were excluded from the study. One woman came for one evaluation session to discuss whether she should seek therapy for her young granddaughter who was not in her care; this women did not wish to discuss anything about herself. A second woman was disorganized, incoherent, and incapable of giving a history; she required immediate hospitalization. A third woman had a history of incest, but my notes were lost. I decided to omit this case from the sample because it could not be documented at the time of chart review.

Seventeen of the 18 patients in the sample were randomly assigned to me by the clinic secretary, who took referral calls and made her assignments on the basis of the clinician's having time available. She had no knowledge of my research and usually had only general demographic and insurance data about the new patient. The remaining patient had met me twice in a way related to my general psychiatric work with children. She specifically requested me as therapist. In a year of twice-weekly therapy, this patient never revealed that she had any knowledge of my work on incest, almost none of which had been published at the time she was in therapy with me.

All of the patients paid for the psychiatric evaluation and, in many cases, for psychotherapy with personal funds, private insurance, or Medicaid. For reasons extraneous to the study, none was covered by CHAMPUS. Fourteen of the women were self-referred or referred by another physician. Two were sent by a social service agency, and 2 others were referred by the court. Thirteen were white, and 5 were black. Thirteen were adults, 3 were adolescents, and 2 were children.

METHOD

In 1977 all of the charts of female patients first evaluated in 1976 were reviewed for a history of incest. I had obtained information in various ways. In some cases, it seemed feasible and appropriate to ask abut an incestuous history while taking a routine sexual history during evaluation. I asked about the sexual attitudes of the patient's subcultural group, extended family, and parents. If the information suggested overt sexual activity in the family, I asked further questions. In other cases, I felt this method was not appropriate or there was no reason to suspect an incestuous history. In these cases I inquired about the possibility of incestuous involvement if material presented during the course of therapy suggested it. For instance, one patient (patient 4) had unusually intense, overtly sexual dreams about a "father figure." When asked about her actual relationship with her father, she revealed an incestuous history. By the time of chart review, most of the patients had been asked about incest. However, I failed to get a sexual history from one young, manipulative adolescent (patient 7) who required hospitalization following a suicide attempt. Since she was coherent and could provide historical data, she is included in the sample.

The social class of the family of each patient was noted to investigate the common impression that incest is primarily a lower-class phenomenon. I estimated social class on the basis of the parents' jobs and the family's social and educational status. This assessment is therefore subjective; no formal assessment was made. In one case (patient 6), the patient's mother was functioning at a social level below that of her family of origin; since the grandparents had assumed primary responsibility for child-rearing, including housing, the child was considered to be in the grandparents' social class.

Intellectual deficits in 2 patients were determined by formal psychological testing.

FINDINGS

Table 1 summarizes the demographic data for the 18 patients. If the case was referred by the court or a social service agency, this is indicated as part of the chief complaint. Nine of the 18 patients were from lower- to lower-middle-class families, and 9 were from middle- to upper-middle-class families.

Six of the patients (33%) gave a positive history of incestuous experiences (patients 1–6 in table 1). Tables 1 and 2 summarize the data on these patients. There was a great deal of marital discord between the parents of these 6 patients which seemed an integral part of the "setting" of incest in these cases. The adults involved were biological fathers in 3 cases and a grandfather, a brother, and an aunt in the other 3. All of the adult participants were full-time residents in the same home as the child at the time incest occurred. All 6 of the cases of incest came from 14 patients who were self-referred or referred by another physician. All were white. Three were from the middle- or upper-middle class, and 3 were from the lower- to lower-middle class. Five were adults and 1 was a young child. None was judged to be psychotic. Only 1 patient revealed the history spontaneously. Two reported incest when asked about it during evaluation, 2 reported it later in the course of therapy when asked, and 1 young child told her grandmother some time later in therapy. Five were seen in psychotherapy, 4 for a period of more than 6 months. Once the accusation had been made (often with great reluctance) none withdrew the charge or changed it substantially.

COMMENT

I could not determine with certainty whether any of my patients who reported a history of incest fabricated the history or how many withheld it. However, it is noteworthy that none of the 4 patients referred by the court or a social service agency fabricated a history of incest to elicit sympathy or to affect her status in the

TABLE 1
Summary of Data on 18 Female Psychiatric Patients

Patient	Age Range	Social Class	Race	Diagnosis	Chief Complaint	History of Incest
1	24–29	Upper-middle	White	Hysterical character disorder	Difficulty concentrating	Positive
2	Over 40	Lower	White	Hysterical character disorder	Marital and sexual difficulties	Positive
3	30–35	Lower-middle	White	Hysterical character disorder	Marital and sexual difficulties	Positive
4	30–35	Upper-middle	White	Hysterical neurosis	Marital difficulties	Positive
5	18–23	Lower-middle	White	Hysterical neurosis	Intense murderous fantasies	Positive
6	Under 12	Middle	White	Adjustment reaction of childhood	School phobia	Positive
7	12–17	Middle	White	Hysterical character disorder	Suicide attempt	Negative
8	24–29	Upper-middle	White	Obsessional character disorder	Problems with girlfriends and boyfriends	Negative
9	24–29	Lower-middle	Black	Hysterical character disorder	Sexual and marital difficulties, depression	Negative
10	30–35	Lower-middle	Black	Depressive neurosis	Marital difficulties	Negative
11	12–17	Lower-middle	White	Character disorder	Court referral; legal difficulties	Negative
12	24–29	Upper-middle	White	Ambulatory schizophrenia	Severe anxiety	Negative
13	24–29	Lower	Black	Character disorder; borderline retardation	Court referral; legal difficulties	Negative
14	12–17	Lower-middle	Black	Retardation	Social service referral	Negative
15	18–23	Middle	White	Hysterical character disorder	Sexual and marital difficulties	Negative
16	24–29	Lower	Black	Hysterical character disorder	Difficulties with family and placement; postlegal difficulties; social service referral	Negative
17	30–35	Middle	White	Hysteria	Depression, sexual and marital difficulties	Negative
18	Under 12	Middle	White	Oppositional character	Sadness	Negative

TABLE 2
Summary of Data on 6 Female Psychiatric Patients with a History of Incest

Patient	Adult Involved	Incestuous Act	Duration of Incest	Age of Patient When Incest Started	How History Revealed	Duration of Therapy
1	Father	Masturbation, cunnilingus, fellatio, and exhibitionism	17 years	8	Spontaneously	More than 6 months
2	Brother	Intercourse	Once	9	During evaluation	None
3	Father	Attempted rape (stopped before penetration)	Twice	13–16	During therapy	4–6 visits
4	Father	Mutual masturbation	Once	12	During therapy	More than 6 months
5	Maternal grandfather	Genital manipulation of child	Unclear—several months to 1 year	5	During therapy	More than 6 months
6	Aunt	Cunnilingus	Weeks to months	5	During therapy, to grandmother	More than 6 months

referring agency. Since most of the patients who reported a history of incest were seen in weekly therapy of at least 6 months' duration, I had an opportunity to observe whether any reports changed significantly over time and whether any were elaborated or withdrawn.

A surprising percentage of this small random sample of female psychiatric outpatients revealed a history of incest when asked. Only 1 patient reported the history spontaneously. Since not all of the patients were seen over an extended period of time, and since half of the patients revealed the history only later in therapy, this is the lowest possible estimate for this sample.

Since 4 of the 6 women who reported a history of incest came from families native to a particular geographic area, it is possible that incest is more common in this geographic area than in others. Although there have been no previous reports of this, two other clinicians in the area commented on the high local incidence of incest, which they had not seen in different

geographic locations. Other clinicians, however, said they saw no more cases of incest in this area than they had seen elsewhere. However, Proctor (9) reported a high incidence of hysteria in children in a neighboring state. He felt this had some connection with the area's religious, antisexual attitudes, combined with practices resulting in early overstimulation of the child, such as permitting the child to sleep in the parents' bed over a period of a number of years. He did not indicate that there were any more overt sexual interactions between the parents and children involved in the symptom formation.

The frequency of incest found in the present study does not appear to be connected to the social class of the patient's family, but it is impossible to know whether this reflects differential reporting patterns. In addition, I have never seen a case of incest involving blacks. Whether this reflects reality or is an artifact of case selection is hard to assess. The *California Sexual Deviation Research* (10) noted lower than expected numbers of blacks among imprisoned sex offenders in the 1950s: although blacks made up 20.5% of all men received at the state prison reception center, they were only 9.9% of all the convicted sex offenders and only 5.6% of all those who committed sex crimes against children. This could be an artifact if, for instance, sex crimes against children were less frequently reported in the black community or incest was less common among blacks because there were fewer intact families. According to a private communication, those who work in black communities see a significant number of cases of incest among blacks. If there are actual differences in prevalence of incest, it again highlights the variability in incest rates among different subcultural groups.

There has been a historical question of whether patient reports of incestuous experiences might be fantasy. I cannot determine with certainty whether the reports of my patients are true because only corroboration by a witness could provide indisputable proof. However, I think that many, if not all, of these reports reflect reality. My associates and I have discussed the basis for this opinion elsewhere (11). Even if half of the reports were false, there would still be an unusually high incidence (17%). If these figures do not reflect a local peculiarity, previous estimates of a history of incest among female psychiatric patients may have underestimated the actual incidence because they relied on spontaneous patient revelations rather than on more direct questioning. Many patients are extremely reluctant to reveal a history of incest, particularly if they feel the evaluator will be shocked or judgmental. All of the patients in this sample had told no one, or at most only one or two close relatives, of the experience. Although it may be possible to "suggest" this history to patients, I tried to avoid this to the best of my ability.

If my conclusion is accurate, it raises the question of whether Freud's early theory that sexual molestation in childhood causes hysterical symptomatology had some merit. This question is particularly pertinent as we grow more knowledgeable about family dynamics and the role of parental seductiveness that stops short of actual incestuous activity. This situation can create striking hysterical symptomatology in the absence of overt action; I have discussed this more fully elsewhere (12, 13).

The effects of the early sexual experiences of these patients are difficult to ascertain. None of the patients was overtly psychotic, and, in terms of social adjustment among the adults, most seemed to have made adequate adjustments, usually similar to those of their parents. There was a high level of marital discord, sexual dissatisfaction, and hysterical characterological disturbance among the patients who had experienced incest. However, it is difficult to assess whether this was related to incest because the patients without a history of incest revealed a similar range and type of symptoms. The effects of incest may be more subtle and related to object relationships (5).

Four of the 5 patients who had experienced incest and who entered psychotherapy benefited (in varying degrees) from therapy. Most of my therapeutic work with these and other patients with a history of incest focused on issues of identity, independence, feelings of safety (14), and the modulation of interpersonal distance (15), not on sexuality. None of the patients in therapy seemed to use her incestuous past to obtain sympathy, although some were seductive in the earlier phases of therapy. Knowing of their past incestuous experience was helpful in understanding some of their feelings and transference reactions.

CONCLUSIONS

It is impossible to make any significant generalizations about the effect of incest on ego structures and object relationships on the basis of this small sample. Only further research will ascertain the effects of early overt sexual experience in the family specifically related to the sexual experience, as opposed to the more general outcomes of grossly disturbed family relationships noted in many incestuous and nonincestuous families. In any case, if therapists become alert to the possibility of a history of incest among their patients, they may be more effective and empathic in their therapeutic endeavors with these patients.

Objective Personality Changes in Residents of a Therapeutic Community

BY JOEL G. SACKS, D.S.W., AND NORMAN M. LEVY, M.D.

The authors tested several groups of drug-abusing young adults who were residents of a drug-free therapeutic community. Three instruments were used: staff ratings, sociometric ratings by members of the community, and MMPI scores. All three measures showed objective evidence of decreasing psychopathology correlated with length of time in treatment, demonstrating the effectiveness of the therapeutic community in the rehabilitation of drug abusers. Individuals who left before completing treatment had MMPI scores indicating inability to develop social relationships; this elucidates a probable cause of the dropout phenomenon.

THE DRUG-FREE RESIDENTIAL therapeutic community is one of the two major methods for treating drug-abusing young adults; the other is methadone maintenance (1, 2). Based on a concept of self-help, the therapeutic community uses positive peer pressure and informal counseling procedures as instruments for personality change. Values that make possible a socially acceptable lifestyle are inculcated by a staff of paraprofessionals (ex-addicts) through a system of rewards and punishments and by the residents themselves through encounter groups that confront individuals with their antisocial attitudes.

This study was done in an attempt to find answers to the following questions: 1) Does the therapeutic community actually produce changes in the personality characteristics of its residents? Although there have been anecdotal accounts of dramatic characterological alterations in individuals who have gone through a therapeutic community (3), it is difficult to find hard data to confirm such changes. 2) Why do some residents drop out within a few weeks of admission and others after 6 or 8 months, while others remain for the complete program of 14 to 18 months?

METHOD

Sample

The Renaissance Project, which is modeled along the lines of Phoenix House (4), serves a predominantly suburban population of drug-abusing young adults. They are drawn from the Westchester County, New York, area. Their median age is 21. They are primarily white (60%), male (85%), and Catholic (45%). Most come from blue-collar, lower-middle-class families (70%). The characteristics of this population have been described in detail elsewhere (5). The majority have used heroin or other opiates.

Design

Because of our stated purposes, a panel study entailing the measurement of residents at two different times was designed and carried out. Over a period of 14 months there were four testing periods, which produced pre- and posttest measures for three different resident groups: 1) group 1, tested in June and October, 1974 (N=20), 2) group 2, tested in October 1974 and March 1975 (N=16), and 3) group 3, tested in March and August, 1975 (N=14). No resident was in more than one group.

The cumulative total of residents tested by this procedure at least once was 114. In addition to the 50 residents who were tested twice, 64 residents received an initial test but did not remain in the program long enough to be retested. There were 44 dropouts in this group. A cross-sectional analysis was conducted on the entire sample of 114 to supplement the test-retest analysis and to offer opportunities to corroborate its findings.

The 114 subjects were divided as follows: cohort 1, 29 residents whose average time in the program at their initial testing was 3 months (range, 0–241 days); cohort 2, 20 residents whose average time in the program was 12 months (range, 242 days–1½ years); cohort 3, 21 residents in the final phase of the program, graduates, and senior staff people, whose average time in the program was 20 months (range, 19–24 months); and the fourth group of 44 dropouts whose average time in the program was 9½ months.

Assessment Procedures

At each test period three assessment procedures were used: staff ratings, sociometric ratings, and the full-scale MMPI. For the staff ratings the staff was

asked to rate resident performance in the five areas of work function, relationships to peers, relationships to staff, participation in therapy programs, and general attitude. Each of these areas was rated on a 5-point scale according to which a rating of 5 signified "very good," a rating of 3 signified "fair," and a rating of 1 signified "very poor." The sum total of ratings received became the resident's score for the time period.

The sociometric procedure consisted of asking the residents to write in the names of peers who in their judgment fell into any of the four following social categories: 1) a person the rater would like to attend a party with, 2) a person the rater considered happy in the program, 3) a person likely to be a leader, and 4) a person considered most unhappy. Each time a resident's name was written in a given category he or she received 1 point. If that resident's was the first name cited, he or she received 2 points; the score was positive for the first three items and negative for the fourth. The total score was the algebraic sum of all scores obtained.

The full-scale MMPI has been used extensively in studying drug addicts and drug abusers. We used the computerized version, which was scored electronically by a testing service.

RESULTS

Table 1 summarizes the results of the test-retest study. Each of the three groups underwent change in the direction of improved adjustment and reduced pathology. Moreover, each of the independent assessment procedures provided confirmatory evidence of this change. Not only was there significant improvement on MMPI scales for each group at the time of retesting, but the staff ratings and sociometric scores also tended to show improvement. One-tailed correlated t tests were used to determine significance.

For each test group the staff ratings at the second testing were higher than at the first. In group 1, the difference of 2.4 points was highly significant (see table 1). For group 3, the .92-point difference approached significance. Only in the case of group 2 was the difference slight and not significant. It is interesting to note that the staff ratings provided the most conservative picture of the degree of change.

Sociometric ratings were available for both testings for groups 2 and 3 (see table 1). Both of these groups showed a large change that was quite significant; for group 2 the second sociometric rating was 14 points higher than the first, and for group 3 it was 10.8 points higher.

Finally, for all groups there was a pronounced pattern of significant change on many but not all of the MMPI scales. These changes were positive and can be interpreted as being in the direction of reduced symptomatology and improved functioning. Thus all three groups showed significant or almost significant reductions in indicators of pathology or, conversely, improvements on measures of health on the infrequency, depression, ego strength, and maladjustment scales. Two of the groups showed a significant improvement on 12 additional scales. These included subtests considered to represent measures of pathology: the anxiety, Iowa manifest anxiety, and schizophrenia scales. In general, we found that changes occurred in the same areas reported by DeLeon and associates (6),

who believed that they represented change in pathological signs.

In the cross-sectional analysis, 8 MMPI scales showed differences of 12 to 18 points between cohort 1 (whose average time in the program was 3 months) and cohort 3 (average time, 20 months) and another 10 differences of 7 to 10 points. In almost all cases the direction of change was in favor of cohort 3, who spent the most time in the program.

These findings seem to suggest a relationship between exposure to the therapeutic community and reduction in pathological symptoms.

In general, dropouts tended to perform in the way one might have expected given their average time in the program (9½ months). Their average scale scores tended to fall in between the ones obtained by cohorts 1 and 2, whose average time in the program was 3 and 12 months, respectively. However, the dropouts scored lower than expected on 4 subscales, 3 of which were found to have no significant correlation with time spent in the program. The fourth was the social introversion (SI-O) scale, which was found to correlate strongly and significantly with the actual sociometric ratings ($r=.33$, $p=.004$); this scale also had one of the strongest correlations with time spent in the program ($r=.46$, $p=.001$).

DISCUSSION

The results of this study show clearly that drug abusers involved in our therapeutic community underwent personality changes in the direction of diminished pathology, and that the longer they stayed in treatment the greater were the alterations according to the MMPI and other instruments. The general configuration of the profiles is quite similar to those obtained by earlier researchers (7, 8): typically, the scores on the psychopathic deviate and hypomania (Ma) scales were above 70 and represented the peaks of the curve.

In our study, the performance curve of the 20 residents who stayed in the program for an average of 12 months approached that of the 21 graduates, but the pattern of the 29 residents who stayed in the program for an average of 3 months had some interesting differences. In the latter group, there was the same tendency to peak at the psychopathic deviate and hypomania scales, but this group also had high scores on the depression and schizophrenia scales. This suggests either of two possibilities: 1) the graduates, being an older generation of drug abusers, had a different pattern of disturbance than the younger group of abusers, or 2) some of the scales, particularly depression and schizophrenia, are more likely than others to change.

A recent study by Zuckerman and associates (9) demonstrated results similar to ours. In the group closest to our sample, which they termed "male hard drug," the pretreatment profile was very much like that of our residents who stayed for only 3 months, with peaks at the depression, psychopathic deviate, schizophrenia, and hypomania scales. The posttreatment profile of this group showed marked drops in the depression and schizophrenia scales, a slight reduction in the psychopathic deviate scale, and virtually none in the hypomania scale, again like our graduate profile. This tends to confirm the suggestion that certain personality elements are selectively affected by involvement in the therapeutic community.

Of particular interest in our study is the lack of any change in the hypomania scale and the MacAndrews scale, which measures tendency toward addiction. These findings suggest that since 2 of the scales that distinguish the addictive profile do not show any improvement, the basic personality substratum of the drug abuser may not be influenced by treatment despite amelioration of symptoms in other areas.

The second major concern of our study was an attempt to elucidate the dropout phenomenon. The dropouts were expected to demonstrate pathological signs to a greater degree than those who stayed in the program when their respective first-test MMPI subscores were compared. In effect, we assumed that the more disturbed members of the community could not be reached by the program and thus would leave it. Instead, we found that the dropouts, in keeping with their average time in the program, tended to fall between the beginners and the residents who stayed in the program. Thus, rather than appearing to be more disturbed than the others, the dropouts seemed to be a group that made some progress and then terminated.

There was one significant exception to the general trend, namely the performance of dropouts on the social participation scale. Here the dropouts did only as well as the beginners. In other words, although the general tendency was to improve somewhat in most areas, in this particular dimension they had not improved at all. This suggests that the crucial factor in the dropout phenomenon is not the overall degree of disturbance but the extent to which the resident is socially accessible to the group experience and capable of achieving some status in relation to peers and other community members.

CONCLUSIONS

Our study demonstrates that there is a definite correlation between length of time in a therapeutic community program and decrease in objective indicators of pathology on the MMPI, staff rating form, and sociometric form. These findings suggest that the therapeutic armamentarium of a therapeutic community such as Renaissance Project is effective in treating drug abusers. Further research is needed to determine the reasons that certain MMPI scales, and their concomitant personality elements, are preferentially improved by involvement in the therapeutic community.

The fact that certain scales on the MMPI that correspond to the underlying character structure of drug abusers did not change suggests that the basic person-

ality configuration was untouched while peripheral pathology was modified, so that the drug-abusing tendency was effectively suppressed. Opposing influences outside the therapeutic community might be expected to have the reverse effect, intensifying psychopathology and causing drug-abusing behavior to recur.

Individuals who dropped out of the program before completion differed from the others mainly in their inability to develop social relationships, as indicated by lack of improvement on a particular MMPI scale that correlated highly with ratings. Thus, initial testing to discover potential dropouts using these instruments would allow extra effort to be brought to bear on such individuals to reduce the risk of their dropping out.

Cognitive and Affective Responses to Lithium in Patients with Organic Brain Syndrome

BY KENNETH H. WILLIAMS, M.D., AND GERALD GOLDSTEIN, PH.D.

The authors describe a series of patients with organic brain syndrome who showed a dramatic clinical response to lithium carbonate therapy. None of the patients had been diagnosed as manic-depressive. Most had extensive psychiatric treatment experiences and had been given both affective and cognitive diagnoses. Six of the eight patients also qualified for the diagnosis of alcoholism. They had been treated with a wide variety of psychotherapeutic medications. Lithium was found to be rapidly and dramatically effective in patients with static lesions of the central nervous system who showed a combination of dementia and agitated depression.

YOUNG AND ASSOCIATES (1) reported on three patients who had manic-depressive illness in combination with organic brain syndrome and who responded well to lithium treatment. The purpose of our report is to summarize the treatment of 10 patients with organic brain syndrome but without manic-depressive illness, 8 of whom also responded to lithium. The organic brain syndromes were well documented and were associated with chronic brain disease of a static or slowly progressive type. Six of the patients were alcoholics (although this was the primary diagnosis for only 2 patients), all had a significant degree of dementia and had a sleep disturbance, and most had a mood state characterized by episodic agitation and dysphoria. Motor restlessness, manifested by pacing or similar rapid, repetitive activity was common.

The effectiveness of lithium in treating patients who have agitated depression, or "mixed mood state," has been documented by Himmelhoch and associates (2). There is also an extensive literature, which has been reviewed by Schou (3) and Kline (4), on the use of lithium to treat alcoholics. Lithium therapy for organic brain syndrome has been discussed by Rosenbaum and Barry (5), Mehta (6), and Taylor and Abrams (7). Jefferson and Greist (8) reviewed the findings for both of these diagnostic groups and concluded that lithium seemed to be effective in alcoholics when a bipolar affective disorder or other cyclic mood disorder was also present and that the organic brain syndrome research was somewhat contradictory but generally positive. Our study was stimulated by this literature and by our experience with the first patient we will describe, whose affect and cognition improved dramatically with lithium after having shown no significant change with other psychotropic medications.

METHOD

Pertinent data on the 10 patients are presented in table 1. The patients were all hospitalized in a large Veterans Administration neuropsychiatric hospital on a ward that specialized in evaluating and treating organic brain syndrome. The ratings in the table are based on clinical observations made by the ward team.

All patients had symptoms of depression, agitation,

8	Korsakoff's syndrome	Mild	Severe	Moderate	Yes	—
Lithium nonresponders						
9	Organic brain syndrome, cardiac arrest	Mild	Severe	Mild	No	Yes
10	Organic brain syndrome, Alzheimer's disease	Moderate	Moderate	Mild	No	Yes

[a]The presence of alcoholism was assessed by record reviews and social histories done on the ward. In some cases alcoholism was not formally diagnosed but was clearly indicated by the records and/or information provided by the patient or relatives.

and sleep disorder. The sleep disorders consisted primarily of difficulty falling asleep, which extended in 1 case to lengthy periods of hyposomnia. Nine patients received CT scans, 6 of which were reported as abnormal. In 4 cases the abnormality was generalized atrophy, but in the other 2 cases there was substantial focal brain damage, resulting in 1 case from a cerebrovascular accident and in the other from a subarachnoid cyst. The 2 patients with substantial damage had received neurosurgical treatment many years previously. Because the patients had long-term chronic illnesses, they had been given numerous anticonvulsant, antipsychotic, and antidepressant medications, none of which was effective—their symptoms persisted and they continued to require hospitalization.

Lithium treatment was carried out in a conventional manner. Before initiation of treatment, patients were given thyroid studies, EEGs, ECGs, and other routine laboratory procedures. The starting dose was typically 900 mg/day, which was raised after a brief period to 1200 mg/day. Blood levels were monitored periodically, and treatment was continued on an indefinite basis. The patients have been maintained on lithium for over a year without notable adverse consequences. When patients were discharged they were advised to continue with the lithium and to report back regularly for monitoring of blood levels.

RESULTS

Of the 10 cases we have described, 6 had clear and dramatic positive responses to lithium. Two patients had partially positive responses that can be viewed as equivocal successes. Lithium treatment was also attempted with two other agitated patients with organic brain syndrome who did not respond at all. One of these patients had experienced acute massive diffuse brain damage associated with cardiac arrest, and the other had advanced Alzheimer's disease. Without a detailed analysis of each case, it is difficult to describe the varied and frequently dramatic positive responses to lithium among these patients. Space limitations do not permit full documentation here[1]; briefly, changes included marked reduction of agitation and pacing, remarkable improvement of memory, particularly in one of the Korsakoff patients, improvement of speech in an aphasic patient, and essential disappearance of abnormal movements in a patient with a severe dyskinesia that resembled Huntington's chorea. We will describe 3 of the more dramatically successful cases.

Case 1. Mr. A, a 52-year-old widowed retired man, was admitted to the hospital after he threatened his son with a knife while he was intoxicated. Mr. A had a history of episodic, unpredictable, violent behavior, multiple hospitalizations, amnesia, confabulation, and denial. He had a 3-year history of difficulty sleeping and a 15-year history of alcoholism. In spite of medical complications associated with drinking, he was unable to remain abstinent and frequently expressed a desire to drink. His medical history included peripheral neuropathy, alcoholic liver disease, and a surgically treated peptic ulcer.

Examination revealed spider angiomata and gynecomastia. He was disoriented to time and place, had a broad-based gait, and peripheral neuropathy. Positive neurologic signs included bilateral graphesthesia, absence of ankle jerks, resting tongue tremor, and positive palmomental, Myerson, and snout signs. Laboratory tests, including liver function tests, were normal, as were the EEG and CT scan. The patient could not recall recent events and in general had

[1]Detailed case histories are available on request from the first author.

an amnesic disorder quite characteristic of Korsakoff's syndrome.

During the 2 consecutive years of his hospitalization Mr. A remained exceedingly agitated, depressed, and irritable. He refused to do anything asked of him, used abusive language, and frequently struck out at people. He was confused, difficult to direct, unable to care for himself, and had episodes of incontinence. He got in and out of bed several times a night. Treatment with chlorpromazine (up to 1000 mg/day) did not control his agitation or relieve his other symptoms.

After initiation of lithium, improvement was noted within 2 weeks. He became quieter and less restless, and his pacing diminished significantly. His sleep was greatly improved and the depressive symptomatology cleared. The temper outbursts essentially disappeared, and he became cooperative, as exemplified by his willingness to take neuropsychological tests that he had belligerently refused previously. These tests revealed moderately impaired function, with normal-range verbal and performance IQs. His incontinence ceased and his self-care improved. Approximately 1 month after initiation of lithium Mr. A returned from a weekend pass and was able to recount, in good detail, where he had been and what he had done. Two months after the initiation of lithium treatment he was discharged home. Under the care of his family he has continued to take his medication and has not been drinking for 1½ years.

Case 2. Mr. B, a 59-year-old retired railroad employee, had a long history of psychiatric hospitalizations dating back to his early 20s. The diagnosis at that time was schizophrenic reaction, catatonic type. The patient also had a history of alcoholism, with alcoholic blackouts, loss of control, and family, legal, and medical problems secondary to drinking. In addition to delusions and hallucinations, he had been consistently described as violent, combative, assaultive, angry, restless, and irritable. He experienced severe recurrent depressions, went without eating or sleeping for extended periods of time, and had made one major suicide attempt. He could not be managed at nursing homes because of episodes of aggressive behavior. In 1972, he underwent surgery to drain a subarachnoid cyst in the parieto-occipital area of the left cerebral hemisphere. After the operation, he had a chronic brain syndrome and a mixed conductive-expressive aphasia.

CT scan and blood flow studies during the present hospitalization suggested a lesion in the distribution of the left middle cerebral artery, and the EEG showed a right cortical focus. Because of the recalcitrant nature of Mr. B's psychiatric and physical pathologies, he received a variety of medications over the years, all with little success, regardless of the amount or combination used. These included three benzodiazepines, four phenothiazines, one butyrophenone, four antidepressants, two anticonvulsants, an antihistamine, and one barbiturate.

It took about 6 weeks for Mr. B to respond to lithium—before this he seemed to worsen. However, after this initial period, marked improvements were noted. There was a dramatic change in affect, and he was described as being more cheerful and less restless. He became more capable of carrying on conversations and had several productive meetings with his wife. Perhaps most dramatically, his aphasia, which had persisted for 5-6 years, seemed substantially improved. Initially, he could only utter a few agrammatic phrases, but he began to speak in normal sentences, albeit with a stutter and some hesitancy. An aphasia could be detected only by specific testing. In view of these marked improvements in affect and in language, Mr. B was discharged home to live with his wife. He has remained well and abstinent from alcohol for over a year at this writing. He continues to take lithium.

Case 3. Mr. C, a 51-year-old unemployed laborer, had had three psychiatric admissions in 4 years for anxiety and depression. He suffered a "stroke" at age 42, with residual aphasia and blindness in the left eye. Over a period of years right and left carotid endarterectomies were performed, with improvement in the aphasia but a residual blind spot in the left eye. Mr. C began drinking heavily at age 18. He had a history of loss of control, blackouts, hospitalizations for detoxification, and family, job, and legal problems related to alcoholism.

Neurologic examination revealed small, irregular, and sluggishly responsive pupils, facial asymmetry, hypesthesia over the upper and lower extremities, and the previously noted blind spot. CT scan showed a large defect in the distribution of the left middle cerebral artery. Three EEGs were abnormal. Neuropsychological tests revealed moderately impaired functioning and an IQ in the low normal range. The patient was treated with individual psychotherapy, three benzodiazepines, a phenothiazine, three antidepressants, an antihistamine, and two sedative-hypnotics, none of which was effective.

Progress notes before lithium was initiated documented the patient's psychopathology with such remarks as "anxiety attack with shortness of breath," "pulse 116," "preoccupied with suicide," "legs and body in constant motion," and "not able to concentrate or retain." One month after initiation of lithium treatment the patient reported that he felt good and was described as being more relaxed and outgoing. The sleep disturbance diminished and he began to read with good retention. The tremor, quavering voice, and other signs of severe manifest anxiety essentially disappeared. Mr. C was discharged and has been doing well at home for a year. He has not resumed drinking and has no complaints of anxiety or depression. This patient's affective and cognitive responses to lithium treatment were remarkably dramatic, perhaps more so than those of any other patient in the series. This patient also is continuing to take lithium.

CONCLUSIONS

We are not proposing that lithium will be effective in all cases of organic brain syndrome with agitation. Our preliminary impression is that patients with severe and diffuse brain damage may not be good lithium responders. However, neither of our nonresponders reacted adversely to lithium.

It is more difficult to explain why the lithium worked than why it did not. Indeed, Himmelhoch and associates have stated that lithium is contraindicated for manic-depressive patients with low-grade dementias or extrapyramidal disorders.[2] One hypothesis might be that lithium-induced reduction in anxiety and agitation

[2]Himmelhoch JM, Licta SM, May SJ, et al: "Age, Dementia, Dyskinesias, and Lithium Response" (unpublished manuscript).

is responsible for the improvements noted in memory and other cognitive abilities. We feel that this is unlikely for two reasons. First, these patients had been given numerous antianxiety agents in high dosages, with no improvement in their cognitive functioning. Second, the changes in cognition were frequently so dramatic that it would be difficult to attribute them solely to stress reduction.

Beyond these considerations, we are at a loss to explain the positive responses to lithium in the successful cases we have described. However, in view of the surprisingly dramatic results, it seemed imperative to report the findings. A controlled, double-blind experiment could not have been performed, and extraneous unidentified variables may have been at work. Nevertheless, the clinical significance of the findings may be enhanced by the fact that we worked with chronic psychiatric patients with long histories of hospitalization. They had been given a wide variety of antipsychotic and antidepressant medications, singly or in combination, none of which effected the improvement seen with lithium. Furthermore, we have also observed relapses (in these and other cases) when the patients stopped taking lithium or took it irregularly. Thus, in a manner of speaking, many of the patients served as their own controls.

Cardiac Sinus Node Dysfunction During Lithium Treatment

BY STEVEN P. ROOSE, M.D., JOHN I. NURNBERGER, M.D., DAVID L. DUNNER, M.D., DAVID K. BLOOD, M.D., AND RONALD R. FIEVE, M.D.

Lithium treatment has been associated with a wide range of cardiac complications. The authors report three additional cases of cardiac sinus node dysfunction due to lithium. Two of the three cases were documented to be lithium dependent by the use of Holter monitoring of cardiac rhythm. On the basis of this finding as well as other reports in the literature the authors recommend careful monitoring of the pulse of patients taking lithium as well as ECG monitoring of patients who are over the age of 50 or who have a history of cardiac disease.

LITHIUM TREATMENT has been associated with an increasingly wide range of cardiac complications. T-wave changes on the ECG, myocarditis, and ventricular arrhythmias have all been reported (1-3). Wellens and associates (4) and Wilson and associates (5) each described a case of reversible sinus node dysfunction. The purpose of our paper is to report three additional cases of sinus node dysfunction, two of which were shown by Holter monitoring of cardiac rhythm to be clearly related to lithium use.

METHOD

All of the patients discussed in this paper were treated as inpatients on the metabolic unit of the New York State Psychiatric Institute. The patients met the diagnostic criteria of Feighner and associates (6) for primary affective disorder. Two of the patients met the criteria of Fieve and Dunner (7) for bipolar I illness, and one patient met these criteria for unipolar illness. Patients were studied only after they gave informed consent to all procedures.

In this series sinus node dysfunction was initially diagnosed by routine ECG and then documented to be related to lithium in two cases by use of Holter monitoring. This procedure records 24 consecutive hours of cardiac rhythm, thereby revealing transitory arrhythmias that might not be discovered by a random ECG. The recording instrument itself is small enough that it can be carried around like a handbag, allowing the patients normal activity during the recording period. Exercise ECG was performed with the patients on a treadmill.

RESULTS

Patient 1

Patient 1, a 69-year-old woman with a history of rapid-cycling bipolar I illness, has been followed in our lithium clinic for the past 10 years. Recently she has been maintained on 600 mg of lithium carbonate q.d.

The patient was admitted to the metabolic unit in a euthymic state for a research protocol. She had a history of hypothyroidism but had been euthyroid for many years on 25 μg of triiodothyronine b.i.d. A recently discovered mild elevation of blood pressure was easily controlled by 250 mg of methyldopa t.i.d. Her admission physical examination was normal. Blood chemistries, electrolytes, complete blood count, thyroid functions, and urine analysis were all normal. The lithium level was 1.0 mEq/liter. A routine ECG, read by our attending cardiologist as normal, showed a sinus rhythm with a rate of 83.

Two months after admission the patient was noted to have a pulse of 40; an ECG taken at that time showed a sinus brachycardia of 40 with occasional junctional escape beats. The lithium level was 1.1 mEq/liter, and the patient's only complaint was mild dyspnea on exertion.

Holter monitoring confirmed a sinus brachycardia with long periods of junctional escape rhythm. During exercise the sinus rate appeared to be incapable of accelerating normally and never exceeded a rate of 80 without exit block and subsequent junctional rhythm. No significant ST-T-wave changes occurred. The patient's lithium was then discontinued. The Holter monitor and stress test were repeated after the patient had been off lithium for 18 days. This time the Holter monitor showed a regular sinus rhythm without arrhyth-

mias, and the stress test showed that the sinus node was able to accelerate to a rate as high as 116/minute without evidence of block.

The patient was then given lithium again; when her level reached 1.0 mEq/liter a third Holter monitoring was recorded. The sinus node dysfunction had returned, as evidenced by long sinus pauses and consequent junctional escapes. The cardiology consultant recommended that if the patient required lithium maintenance a permanent cardiac pacemaker be implanted. The patient recognized that lithium treatment had been essential to her mood stability and agreed to a pacemaker implantation. Two months after the implantation the patient was living at home in a euthymic state and without cardiac symptoms.

Patient 2

Patient 2, a 75-year-old man with a 30-year history of bipolar I illness, has been followed in our lithium clinic for 9 years and has been stable on a maintenance dosage of 1200 mg of lithium q.d. The patient had no clinical history of cardiac disease, but a routine ECG in the clinic showed a normal sinus rhythm with a left bundle-branch block and evidence of an old anterolateral myocardial infarction. His ECG findings had been unchanged for 9 years.

After the patient abruptly went on a salt-restricting diet, he developed ataxia and choreiform movements of the fingers and hands. His lithium level was 1.8 mEq/liter when he was admitted to the metabolic research unit.

Physical examination on admission showed that he was alert, that his blood pressure was 130/80, and that his pulse was 40. There was slurring of speech, gross ataxia when walking, and the choreiform movements previously noted. Blood chemistries, electrolytes, complete blood count, and urine analysis were all normal. An ECG showed a sinus brachycardia of 35, with periods of a junctional escape rhythm. There was a left bundle-branch block configuration and T-wave inversions in leads II, III, AVF, and V4-V6.

The patient was transferred to the cardiac intensive care unit. Atropine (1 mg I.M.) was given without effect. Following 18 hours of hydration the patient's lithium level had fallen to 1.5 mEq/liter and his heart rhythm then stabilized at normal sinus, with a rate of 60. The T-wave inversions in leads V4-V6 persisted. Subsequent ECGs all showed normal sinus rhythm, with rates of 60–80/minute.

The patient recovered uneventfully from this episode of lithium toxicity but refused Holter monitoring. Lithium maintenance was resumed (600–900 mg q.d.), and he was discharged from the hospital with instructions to take his pulse twice a day. Through 2 years of follow-up he had only one episode of transitory sinus brachycardia.

Patient 3

Patient 3, a 53-year-old woman, had a 15-year history of recurrent unipolar depressions. She was admitted to the metabolic research unit for treatment of an acute depressive episode. She had no history of cardiac disease.

Admission physical examination was normal. Blood chemistries, electrolytes, complete blood count, and urinalysis were all normal. ECG was read as normal and showed a normal sinus rhythm, with a rate of 72.

The patient was treated with lithium and tricyclic antidepressants for 3 months without medical complications but also without a satisfactory clinical response. The medications were stopped and the patient was given a course of ECT; moderate improvement followed. Lithium treatment was resumed. After 4 weeks an ECG showed sinus node dysfunction, evidenced by an irregular sinus rhythm with pauses up to 1.6 seconds followed by junctional escape beats. The patient's lithium level was .71 mEq/liter.

Lithium was discontinued and the patient was kept off medication for 16 days. A Holter monitor recording showed a normal sinus rhythm, with a mean rate of 72/minute. Lithium was resumed and stabilized at a level of 1.0 mEq/liter. A repeat Holter monitoring showed that the sinus node dysfunction had returned. The patient was taken off lithium; 2 months later there was no ECG evidence of sinus node dysfunction or other cardiac symptoms.

DISCUSSION

It is known that lithium enters the cardiac cell, displacing cations and creating intracellular metabolic changes, including hypokalemia. These electrolyte shifts are thought to be the physiological processes underlying the T-wave changes seen on the ECG during lithium treatment. However, the mechanism by which lithium influences cardiac conduction is still obscure. Riciutti and associates (8) showed that when doses of lithium as high as 300 mg/kg of body weight were given intravenously to animals, ventricular and atrial arrhythmias as well as prolonged AV node and intraventricular conduction times occurred. Paradoxically, a review of animal studies by Tilkian and associates (9) demonstrated a possible antiarrhythmic effect of lithium. The pathophysiology of spontaneously occurring sinus node dysfunction is not yet established. The pacing cells of the sinus node are in part dependent on calcium ion flux for their generative capacity, and it is possible that lithium-induced sinus node dysfunction may be related to alterations in calcium ion flux.

Tilkian and associates (9) referred to sinus node dysfunction and ventricular arrhythmias as complications that occur rarely in lithium-treated patients. However, in a report on the results of exercise testing and prolonged ECG recordings in 12 patients on and off lithium, the same group (10) observed that 3 patients had increased ventricular ectopy on lithium. It is likely that cardiac arrhythmias are a more frequent complication of lithium treatment than originally suspected, especially in view of the fact that in one earlier case and in

all of the patients reported in this study the sinus node dysfunction was asymptomatic. Furthermore, as the three cases reported here indicate, the complication of sinus node dysfunction can occur during any of the stages of lithium treatment, e.g., the initial phase, after many years of uncomplicated treatment, or during an episode of toxicity. Therefore, we recommend that the pulse of patients on lithium be regularly recorded and that semi-annual ECGs with long rhythm strips be taken on all lithium-treated patients who are over the age of 50 or who have a history of cardiac disease.

Variable Attenuation of Amphetamine Effects by Lithium

BY BURTON ANGRIST, M.D., AND SAMUEL GERSHON, M.D.

In an open study of 8 subjects, approximately half showed some attenuation of CNS stimulant effects of amphetamine after pretreatment with lithium. Two showed specific blockade of euphoria, with persistence of some CNS stimulant effects. In 3 subjects lithium did not appear to affect the response to amphetamine. Lithium caused significant attenuation of the amphetamine-induced increase in systolic blood pressure for the group as a whole.

TWO REPORTS to date have indicated that in some cases the effects of amphetamine can be diminished by chronic lithium treatment. Flemenbaum (1) retrospectively documented 3 cases in which this occurred: 2 amphetamine abusers spontaneously gave up the drug because of loss of "high" feelings after starting lithium treatment for affective disorder; the third took amphetamine for dieting and noticed a blockade of both subjective affects and anorexia after receiving lithium. Van Kammen and Murphy (2) reported a double-blind placebo-controlled study in which the effects of 30 mg of *d*- or *l*-amphetamine were observed in 9 patients with moderate to severe depression before and after a minimum of 10 days' lithium treatment. They found a 60% attenuation of activation and euphoria induced by the *d* isomer and almost complete abolition of the effects of *l*-amphetamine after lithium administration. We conducted the open study described here to assess the effect of lithium on the response to amphetamine of subjects without overt affective disorder under conditions of direct observation.

METHOD

Our proposed project was explained to patients admitted to Bellevue Psychiatric Hospital for a variety of reasons who had some familiarity with amphetamine effects. Eight patients who were willing to participate and who provided informed consent were transferred to a research ward, treated as indicated by their individual condition, and then stabilized off all medica-

0002-953X/79/07/0806/05/$00.50 © 1979 American Psychiatric Association

tions for 6–24 days before participating in the study. D-Amphetamine (1/2 mg/kg) was given orally twice—before and after 6–15 days' treatment with lithium. The amphetamine response was assessed by the following methods: 1) taking pulse and blood pressure after the patient had been lying quietly for 5 minutes before amphetamine administration and at hourly intervals after amphetamine was given, 2) unstructured clinical notes before amphetamine administration and hourly after, 3) filling out the amphetamine subscale of the Addiction Research Center Inventory (ARCI)—38 true-false items that have been shown to discriminate amphetamine from placebo at the .05 level of significance (3)—before and 3 hours after drug administration, and 4) giving the 100-millimeter line, an index of self-assessment of euphoria, before and 3 hours after amphetamine was given (in 2 cases the ARCI and the 100-mm line were unfortunately omitted at baseline; in these 2 cases raw scores rather than pre-post drug change scores are reported).

These parameters of the amphetamine response "on" and "off" lithium were compared. The study was not blind, and neither lithium placebo nor amphetamine placebo was used.

RESULTS

The parameters of response described above to a fixed dose of 0.5 mg/kg *d*-amphetamine are indicated in table 1, which shows the responses of the patients before and after lithium administration.

Patient 1 was a 19-year-old man with a diagnosis of antisocial personality who entered the hospital because of a mild amphetamine psychosis. The patient had taken 100 mg of *d*-amphetamine "to cause a heart attack." He received lithium for 15 days (maximum dose, 3000 mg/day). At the time of testing, his lithium level was 1.24 mEq/liter. According to the clinical notes, this patient was more talkative, evasive, and histrionic while off lithium. On lithium, he was "in love with mankind" and bought potato chips for the other patients. He said he had felt "crappy" by comparison the last time he got amphetamine: "Wow! I love you for this." The global clinical impression was that he was definitely more euphoric on lithium.

Patient 2 was a 24-year-old man diagnosed as having acute reactive depression and a passive dependent personality. He received lithium for 12 days (maximum dose, 2100 mg/day). His lithium level was 1.59 mEq/liter at the time of amphetamine administration and 1.24 mEq/liter 3 hours after that. Off lithium he was markedly more animated and talkative and was optimistic, confident, and energetic. He had definite euphoria and some palpitations, clenching of teeth, and "tingling" of scalp. On lithium he was irritable and "edgy" and had rapid speech. He preferred to remain withdrawn and felt "physically hyped up, but it's like my engine is revving. The positive feeling and confidence isn't there." He was somewhat self-dramatizing and provocative but had no palpitations or clenching of teeth. The global clinical impression was that euphoria was blocked but dysphoric stimulation persisted on lithium.

Patient 3 was a 53-year-old man with a history of habitual excessive alcohol use who was admitted for detoxification. He received lithium for 6 days (maximum dose, 3000 mg/day). His lithium level was 1.16 mEq/liter at the time of testing. Off lithium he was talkative and euphoric. He noted philosophical concerns: "It's like a religious experience—the exact opposite of alienation." He spoke of John Donne, theories of love, and "the nature of truth." On lithium he felt a "muted effect." He had no "push" toward philosophizing as he had before. He continued to read with pleasure, and his concentration was increased. He appeared relaxed and euphoric. The global clinical impression was that lithium attenuated psychological and cardiovascular amphetamine effects.

Patient 4 was a 35-year-old man with a diagnosis of episodic excessive alcohol abuse who was admitted for detoxification. He received lithium for 6 days. This was discontinued for 24 hours because of possible toxicity, and then lithium was given for another 6 days before testing (maximum dose, 3000 mg/day). His lithium level was 1.0 mEq/liter. Off lithium he appeared calm but more talkative. He said he felt "serious" and "at peace with the world." At times he was slightly tangential. On lithium he stated he felt "calm but energetic." He was talkative, intense, and introspective. At times he had a wide-eyed "stare." The global clinical impression was that there was no clear difference in the effects of amphetamine after lithium administration.

Patient 5 was a 19-year-old woman two took amphetamine and cocaine intravenously and was admitted because of an amphetamine psychosis. The only diagnosis assigned her was drug dependence, specifically dependence on CNS stimulants. She was given lithium for 6 days (maximum dose, 2000 mg/day). Her serum lithium level was 1.14 mEq/liter. Off lithium she had increased libido, increase in "tender" feelings, and emotional lability. She said she felt "terrific." She enjoyed talking with other patients and showed pressure of speech, some tangentiality, and circumstantiality. On lithium, she was calmer, less intense, and in better control: "I can keep my mind on one thing." There was no objective circumstantiality or tangentiality and no increase in libido: "I'd say you gave me half the dose as last time." She felt this dose was "perfect" and wouldn't take more. The global clinical impression was that the effects of amphetamine were attenuated after lithium administration but that there was no specific blockage of euphoria.

Patient 6 was a 49-year-old man diagnosed as having antisocial personality with habitual excessive drinking. He was admitted after causing a disturbance while drunk. He received lithium for 7 days (maximum dose, 2400 mg/day); his serum level was 1.11 mEq/liter at the time of testing. Off lithium, he was more talkative; his

[a]A fixed dose of 0.5 mg/kg of *d*-amphetamine was administered.
[b]The amphetamine subscale of the Addiction Research Center Inventory (ARCI) contains 38 true-false items that have been shown to discriminate amphetamines from placebo.
[c]The 100-mm line is an index of self-assessment of euphoria.

mood was serious and earnest: "My problems are there but I don't worry about them." He felt more "sentimental" and "creative" and wrote a poem about New York City. On lithium, he was again more talkative: "It takes the gloom away. I know the problems are there but they don't bother me." He felt he had increased "fertility power" and an increased sense of smell (he "smelled women"). He said he had "no worries." The clinical global impression was that there was no clear change in amphetamine effects after lithium administration.

Patient 7 was a 29-year-old man who was a heavy user of intravenous cocaine. He was admitted because of suicidal ideation and diagnosed as having a passive-aggressive personality with cocaine dependence. He received lithium for 7 days (maximum dose, 1800 mg/day) and had a serum level of 0.7 mEq/liter at the time of testing. Off lithium he felt he had an increased sense

[c]The 100-mm line is an index of self-assessment of euphoria.
[d]Significantly ($p<.01$) elevated over baseline.
[e]Change score significantly ($p<.05$) smaller off lithium.
[f]Significantly ($p<.05$) elevated over baseline.

of smell. He felt "benevolent" and was emotionally labile: "I see other patients talking and laughing and I think of not knowing what friends or family are." On lithium he felt his sense of smell was again increased. He felt more "empathy" and was again emotionally labile: "I feel I want to grab your arm and say 'thank you.' " Ideas seemed "more important." The global clinical impression was that there was no clear change in amphetamine effects after lithium administration.

Patient 8 was a 32-year-old man diagnosed as showing an inadequate personality with alcohol addiction. He received lithium for 8 days (maximum dose, 1750 mg/day) and had a serum level of 1.0 mEq/liter at the time of testing. Off lithium he said he felt "nice," "lively," and "not depressed." He snapped his fingers while talking. He was animated, and his reaction time was decreased. On lithium, he felt "nervous," "jittery inside," and "jumpy": "not at all like last time." His animation was not increased, and his reaction time was not decreased. The global clinical impression was that euphoria was blocked; there was some attenuation of stimulant effects.

Statistical analysis of pooled data (see table 2) indicated that the amphetamine-induced increase in systolic blood pressure was significantly less after lithium administration ($t=2.93$, $p<.05$, two-tailed). Increases in diastolic blood pressure and changes in pulse rate were not significantly different after lithium, nor were change scores on the ARCI and the 100-mm line (for the 6 patients for whom these data were available). Scores on the 100-mm line were significantly elevated after amphetamine alone but not significantly raised by amphetamine after lithium. However, the change scores from baseline were not significantly different before and after lithium.

DISCUSSION

Lithium caused significant attenuation of the amphetamine-induced increase in systolic blood pressure. Since it is generally assumed that the pressor effects of amphetamine are mediated by norepinephrine, this finding is consistent with a study by Fann and associates (4) in which lithium was found to attenuate the pressor response to norepinephrine itself in manic patients.

Lithium was also found to affect the subjective and behavioral effects of amphetamine variably in different subjects. This variability and the small number of subjects in this study in all likelihood account for the failure of the ARCI and 100-mm line to show significant changes (the stimulant subscale of the ARCI, in particular, has been shown to discriminate amphetamine effects reliably [3], but in a large number of subjects). Our individual subjects' response patterns can be summarized as follows: 3 subjects showed no clear difference in amphetamine response after lithium, 2 showed attenuation of stimulant effects after lithium, 2 showed a blockade of euphoria but persistence of dysphoric stimulation, and 1 was more euphoric after lithium and amphetamine than after amphetamine alone.

Although it may seem contradictory, the response of this last subject might also represent attenuation. Several investigators (5–7) have noted that the euphoria occurring after low doses of amphetamine or cocaine is replaced by dysphoric feelings after the dose is further increased. Thus a decreased responsivity on the basis of lithium pretreatment could lead to a euphoric response to a dose that was "too high" to cause this effect originally. If this subject's response is accepted as a type of attenuation, then 3 of the subjects could be considered to show this response pattern, while 3 showed no change in amphetamine response on the basis of lithium pretreatment and 2 experienced a selective blockade of euphoria. The patients who showed either attenuation of stimulant effects or blockade of euphoria received lithium for a mean of 8.25 days and had a mean plasma level of 1.22 mEq/liter. The patients whose amphetamine response was unaffected by lithium received lithium for 8.66 days and had a mean plasma level of 0.94 mEq/liter. The patient whose response was open to interpretation (ei-

ther increased euphoria or attenuation) received lithium for 15 days and showed a serum level of 1.24 mEq/liter. It seems unlikely that those small differences can account for the variable effects on amphetamine response observed. It is possible, however, that more consistent findings might have resulted from a longer lithium pretreatment period.

These findings are consistent with those of van Kammen and Murphy (2) in their controlled study of depressive patients. Although they stressed the highly significant attenuation of euphoria and activation for the group as a whole, their subjects' individual response patterns showed similar variability (3 of their 9 subjects showed no diminution of activation and 5 showed only slight or no decrease in euphoria). Thus the effects of lithium on the amphetamine response appear to be similar in both populations studied.

These findings are also consistent with preclinical studies in which attenuation of amphetamine effects by lithium have been noted. These include decreased effects on intracranial self-stimulation (8) and locomotor activity (9).

The mechanisms underlying this partial and inconsistent "antagonism" are unknown. Neurophysiological studies by Buchsbaum and associates (10) have shown that amphetamine-induced changes in visual average evoked responses correlate with the degree of euphoria and activation seen after amphetamine and that these changes are also attenuated by lithium, suggesting a possible common mechanism. However, both amphetamine and lithium have effects on many brain systems (11, 12) and therefore could interact in many ways. Aminergic neurotransmitter systems have been studied to some degree. Friedman and Gershon (13) have shown that treatment with lithium for 2 weeks causes a decrease in dopamine synthesis in rat brain.

Berggren and associates (14) have demonstrated that the decrease in amphetamine-induced locomotor stimulation caused by acute lithium pretreatment could be reversed by a small dose of L-dopa, which had no effect on locomotor activity per se, further suggesting a catecholaminergic mechanism, possibly involving decreased synthesis. According to a personal communication, the same group has also demonstrated decreased dopa formation (after inhibition of decarboxylase) after acute lithium, suggesting a similar mechanism. However, lithium also has complex time-dependent effects on serotonin biosynthesis, some parameters of which are directly antagonized by acute cocaine administration (15). Thus, effects on aminergic neurotransmitter systems may underlie this drug interaction, but it is difficult to specifically implicate catecholaminergic or serotonergic mechanisms. Indeed, effects other than those on aminergic neurotransmitters might also mediate this interaction.

Mandell and Knapp (15), van Kammen and Murphy (2), and Flemenbaum (1) have all suggested that lithium might prove clinically useful in the treatment of stimulant-dependent patients. The results of this study suggest that this might be the case in patients in whom lithium attenuates the effects of stimulants (perhaps 50% based on this small sample). Such patients would of course have to be highly motivated to discontinue stimulant use in order to ensure reliable lithium intake; many stimulant users are not motivated in this way. Nonetheless, lithium might prove a useful adjunct, particularly in the early phases of discontinuation when craving is most severe (i.e., the first few months). Since no specific treatment for stimulant dependence exists, lithium may be of some potential benefit to this small patient group.

Lithium Plus Reserpine in Refractory Manic Patients

BY NORMAN M. BACHER, M.D., AND HARVEY A. LEWIS, M.D.

The authors report on six refractory manic or schizo-affective manic male outpatients who failed to respond to lithium combined with a neuroleptic. A beneficial response was noted in most patients when reserpine was substituted for their currently prescribed standard neuroleptic; in some cases lithium dosage could then be reduced. No major side effects were encountered. The use of reserpine may offer an alternative mode of therapy for manic patients who cannot tolerate large doses of lithium or do not completely respond to lithium either alone or in combination with a standard neuroleptic.

WHEN THE USE of reserpine in American psychiatry markedly diminished after 1960 (despite its usefulness in some psychotic conditions), postsynaptic dopamine-blocking neuroleptics and antidepressants became generally accepted, although lithium had not yet been introduced in this country for the treatment of manic-depressive illness. In the 1960s investigators reported on the use of antiserotonin agents in mania (1). Reserpine, which has antiserotonin properties, has been reported to be of value in manic, catatonic, and excited states (2). Although lithium has been tried alone and in combination with various neuroleptics in many refractory, cyclic, and affective states, we have found no reports of clinical studies combining lithium with reserpine (3).

In our Veterans Administration outpatient clinic we have encountered a number of agitated, excited outpatients diagnosed as manic-depressive or schizo-affective manic who do not respond to therapeutic levels of lithium alone or to lithium plus neuroleptic. This report describes six such patients; in a clinical trial we added reserpine to the patients' lithium dosage and reduced or discontinued neuroleptic after discussion with the patients concerning this mode of treatment. These patients were considered refractory (i.e., unmanageable) at the time that reserpine was added.

We told each prospective patient of reserpine's use in psychiatry and its gradual disuse after the newer major tranquilizers became established as more effective. We explained that we had used reserpine in disturbed and excited patients, that it has been approved by the Food and Drug Administration as a relatively safe psychiatric drug, and that it is still widely used in the medical treatment of hypertension. We told them that we felt reserpine plus lithium might be more effective than their current tranquilizer plus lithium, since they had not done well on that combination. Each patient was cautioned that this new combination of reserpine plus lithium had not, to our knowledge, been tried previously. If they agreed, we followed them closely, only adding reserpine gradually and watching for side effects. The patients were told to stop taking reserpine and contact us if any undesirable side effects occurred. We discussed major side effects and known contraindications of reserpine with each patient.

METHOD

All six outpatients showed the following characteristics. Diagnosis was manic-depressive, manic, or excited schizo-affective. The behavioral component of the illness was at least as marked as the thinking disorder, and the patients tended toward denial, elation, overstimulation, hyperactivity, argumentativeness, and pressure of speech with tangential, circumstantial, and irrelevant thought processes. Delusional qualities of thinking, both grandiose and paranoid, were prominent, although the former seemed more pronounced. These delusional ideas were reflected in the behavioral manifestations of the illness and persisted, although they were diminished in patients who improved, throughout the course of treatment. All patients had sexual identification problems and latent to overt acting out character defenses. A tendency toward social pathology was prominent. On a pragmatic level these patients at times were loud and boisterous, attended clinic frequently but irregularly, tended to disrupt clinic routines, and became easily involved in verbal, hostile, and sadistic exchanges with staff and other patients.

Four of the six outpatients had had several recent psychiatric hospitalizations during which they had ap-

parently responded adequately to therapeutic levels of lithium plus neuroleptic. However, as outpatients they decompensated rapidly despite apparent continuation of the same levels of medication. Their manic symptoms may have been aggravated by alcohol or drugs or possibly by noncompliance. The other two manic outpatients, one in day care, could not be stabilized despite frequent contacts with staff and therapeutic levels of lithium plus a neuroleptic.

All six patients at times complained of their medication, especially the neuroleptic. Some complained of side effects of the lithium, such as gastrointestinal symptoms, tremors, and urinary frequency. One patient developed tardive dyskinesia while taking a neuroleptic. In most of these patients lithium levels were obtained frequently and found to be in a therapeutic range even during delusional thinking overactivity.

The issue of noncompliance is a problem with these patients, and we found that the oral lithium dose cannot accurately be correlated with blood levels from patient to patient. One patient rarely came to the laboratory to have blood drawn. Overall, the lithium-neuroleptic combination was a failure in all six cases. The literature indicates that a substantial number of patients taking lithium fail to improve or relapse and become chronic (4, 5).

RESULTS

Reserpine in dose ranges of 0.25 to 1 mg/day (up to 8 mg/day for 1 patient) was added to the lithium dosage for a short time while the neuroleptic was gradually eliminated. Response over a period of one to two weeks was marked, appeared dose-related, and affected the disruptive behavioral component of the illness more than the thinking process. The patients became calmer. Once reserpine was begun, lithium dosage in most of the patients was adjusted downward; in two patients there was remission with lithium levels below the currently accepted therapeutic range, although spontaneous remission could not be ruled out. If some dysphoria developed, reserpine dosage was adjusted or given intermittently or at night. However, there are indications that lithium may be protective against reserpine dysphoria. Experimental work shows that lithium prevents reserpine depletion of neurotransmitter amines from the presynaptic ganglion (6).

We have followed most of these six refractory patients as outpatients periodically over several years. Improvement occurred in all patients when reserpine was given with the lithium; in most patients, greater compliance and adjustment resulted. One patient's behavior improved slightly on reserpine-lithium, but he continued to experience severe thought disorder, which suggested a diagnosis of chronic schizophrenia.

Although these are observational data, two of these six refractory patients have become tractable and cooperative compared to their prereserpine state and are no longer a management problem. Since these patients are doing well, we did not selectively withdraw one or the other medication to differentiate the effect. In the two improved patients we reduced lithium dosage when lithium was combined with reserpine, and remission was maintained. This is important because lithium and neuroleptics have been increasingly reported as having serious long-term side effects.

CASE REPORTS

Case 1. This 32-year-old married unemployed male outpatient remained hyperactive, talkative, elated, loud, overstimulated, disruptive, and grandiose during frequent but irregular visits to the clinic for over 1 year. He felt he was receiving messages from the planets and stars. Although in a recurrent manic state, he had not been hospitalized. He responded poorly to various combinations of neuroleptics alone or with lithium in therapeutic dosage. Compliance and illicit drug use were unknown factors. We recorded few serum lithium levels. However, in recent months with medication changed to lithium and reserpine, this outpatient began to improve dramatically, both affectively and behaviorally. He now attends the clinic regularly, is on lithium, 900 mg/day, and reserpine, 0.75 mg/day. He remains calm and clear and intends to train for an occupation. We cannot rule out a spontaneous remission, but his improvement coincided with a lithium-reserpine combination.

Case 2. This 48-year-old married man had a stable work and marital history. However, over the previous 2 years, he has had several psychiatric hospitalizations and was diagnosed as manic-depressive each time. After some months, he would stabilize in the hospital on lithium and a neuroleptic, but as an outpatient he would quickly become hyperactive, argumentative, and elated, demonstrate some paranoid ideation, and be difficult to manage. Stresses on him as an outpatient may have resulted in an increase in alcohol consumption and noncompliance regarding lithium. After the most recent discharge, he complained of the side effects of both lithium and the neuroleptic. We stopped the neuroleptic and added reserpine up to 1 mg/day with gradual reduction in the lithium dosage to 900 mg/day. Repeated lithium levels have been at 0.3–0.4 mEq/liter. Over several months, the patient became compliant, worked on marital conflicts, and returned to his job. He remained stable for about six months but began to drink after experiencing new work stress. His mood became elevated; he discontinued work and was again seen frequently in the clinic. His reserpine dosage was adjusted to 0.75 mg/day, and he continued on lithium, 900 mg/day. A recent serum lithium level was 0.3 mEq/liter. The fact that he did well on small doses of lithium and reserpine for some 6 to 8 months suggests synergistic action and enabled us to reduce the lithium dosage. After recently becoming more disturbed, unrealistic, and noncompliant, he was rehospitalized.

Case 3. This 32-year-old single man has had repeated psychiatric hospitalizations over the past 10 years. He has received large amounts of various neuroleptics plus lithium. In recent years, his diagnosis has been more often manic or schizoaffective, with a depressive component. When seen as an outpatient, he has been loud, demanding, overstimulated, grandiose, and delusional. He insisted he was the Messiah

and could cure all mental illness and evil and prevent death. His few stable periods, during which he was out of the hospital, lasted only a few months. Some months later, he was again discharged on lithium and neuroleptic medication. His blood levels (1.0 mEq/liter) showed lithium compliance; however, he remained elated, hyperactive, grandiose, severely psychotic, and a management problem despite frequent contacts with the clinic. He complained of dysphoric effects from the neuroleptic. Reserpine was added to the 1200 mg/day of lithium, and neuroleptic medication was gradually discontinued. He was less disturbed for a time on reserpine and lithium. When reserpine was increased to 6.0–8.0 mg/day and lithium remained at therapeutic levels, his overactivity was markedly reduced within one week. He became quiet and seemed less certain of his grandiose delusions. However, because of complaints of sluggishness and dysphoria, the reserpine was gradually reduced and the patient soon became more disturbed and was rehospitalized. Large doses of reserpine combined with lithium were helpful and did not result in depression.

Case 4. This 28-year-old recently separated unemployed man came to our clinic in crisis demonstrating depression and delusions about astrology and ESP. On neuroleptic combined with antidepressant, the patient became hyperactive and required a first psychiatric hospitalization. He was diagnosed as manic-depressive and discharged on lithium and chlorpromazine. A few weeks later he returned to the clinic stating he had reduced his medicine significantly, preferring euphoric feelings. He disliked medication, especially chlorpromazine. We encouraged the use of at least some lithium plus small amounts of reserpine. The patient later reported the use of lithium over several months and reserpine on an as-needed basis. He said reserpine quieted him and lithium helped the feelings in his head. The patient has since returned to work and resumed group therapy. His current lithium dosage is 300–600 mg/day in addition to 0.25–0.5 mg/day of reserpine. It appears the low dosage of this combination helps to maintain his remission. The lithium and reserpine seem to have different antipsychotic properties in addition to being synergistic. He continues to maintain his remission.

Case 5. This 56-year-old divorced man with a long history of recurrent manic-depressive episodes had a manic attack while in our day center. He was placed on therapeutic levels of lithium plus a neuroleptic to control his hyperactivity and elation. When parkinsonism and tardive dyskinesia developed the neuroleptic was discontinued and reserpine up to 1.0 mg/day was added to the lithium. The lithium level remained in a therapeutic range. The patient soon became rational and stable, and his dyskinesia and parkinsonism improved slightly. For a few months on a regimen of lithium, 900 mg/day, and reserpine, 0.5 mg/day, he made a better dependent adjustment in the day center than at any time in the prior 10 years. Reserpine was used intermittently and then gradually withdrawn in order to control dysphoric symptoms. His lithium levels were 0.4 mEq/liter. Recently, on no reserpine and with the lithium level at 0.6 mEq/liter, the patient had another mood swing that required a brief hospitalization despite the use of a standard neuroleptic.

Case 6. This 30-year-old single male graduate student has been seen periodically over the years. He has often been emotionally labile and affected by alcohol. His diagnosis is recurrent mania, and he seems to do well on lithium when hospitalized and poorly on lithium as an outpatient. Under stress in the community, he discontinues medication, becomes delusional (feeling he is involved in an undercover plot involving murder), loses control, and is hospitalized frequently. A few months ago he returned to the outpatient clinic in remission after another brief hospitalization. He was on lithium, 1200 mg/day, with a therapeutic blood level but had discontinued chlorpromazine. He was persuaded to substitute small doses of reserpine (up to 0.75 mg/day) for the chlorpromazine and continue on lithium. He remained stable, returned to school, and tolerated the lithium well with small amounts of reserpine for a short time. However, despite therapeutic blood levels of lithium at a dosage of 1200 mg/day, he again demonstrated paranoid ideation and was manipulative. Because we could not be sure of compliance, he was rehospitalized. When he returned to the clinic, we learned that he had taken the reserpine for only a few days.

DISCUSSION

These cases demonstrate that reserpine combined with lithium may be more effective than lithium with a neuroleptic or lithium alone in certain intractable affective disorders and may provide an alternative when a patient responds poorly to lithium with a neuroleptic.

Because lithium affects brain neurotransmitter amines and is homeostatic on mood and reserpine depletes brain neurotransmitter amines presynaptically and has a tendency to produce sedation and release depression-like states, they may be synergistic in mania. Further, some reports note a relationship between mania and hypertension (7), and reserpine is a well-known antihypertensive. Recently, articles have appeared indicating that catatonic, paranoid, and affective conditions may belong to an affective spectrum (8, 9) and that lithium should be tried in refractory affective and even refractory schizophrenic states (10). In view of our observations, we suggest that reserpine can be used effectively in combination with lithium in treating certain affective conditions refractory to lithium or lithium combined with a neuroleptic.

We have noted few side effects from the reserpine-lithium combination. All our patients were normotensive, and reserpine does not usually lower blood pressures below normotensive levels. Dysphoric symptoms, such as dizziness, weakness, tiredness, and fatigue were easily reduced by adjustment or intermittent use of reserpine. A switch to depression did not occur, possibly because lithium's antidepressant effects protected against depression. We have not as yet tried this combination in similar patients, but we feel further clinical trials and controlled studies are indicated.

BRIEF COMMUNICATIONS

DSM-III Field Trials: I. Initial Interrater Diagnostic Reliability

BY ROBERT L. SPITZER, M.D., JANET B.W. FORMAN, M.S.W., AND JOHN NEE, PH.D.

The interrater agreement for major diagnostic categories in studies using DSM-I *and* DSM-II *was usually only fair or poor. In phase one of the* DSM-III *field trials the overall kappa coefficient of agreement for axis I diagnoses of 281 adult patients was .78 for joint interviews and .66 for diagnoses made after separate interviews; for axis II—personality disorders and specific developmental disorders—the coefficients of agreement were .61 and .54. The interrater reliability of* DSM-III *is, in general, higher than that previously achieved and may be due to changes in the classification itself, the separation of axis I from axis II conditions, the systematic description of the various disorders, and the inclusion of diagnostic criteria.*

PREVIOUS STUDIES of the reliability of psychiatric diagnosis using the first and second editions of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-I* and *DSM-II*) have indicated that for the major categories, such as schizophrenia and affective disorder, the interrater agreement was usually only fair or poor (1). An important step in the development of the third edition of the *Diagnostic and Statistical Manual* (*DSM-III*) has been a series of field trials using draft versions of the manual. One of the most important purposes of the major field trial, sponsored by the Division of Biometry and Epidemiology of the National Institute of Mental Health, has been to determine interrater diagnostic reliability. In this paper we present the interrater diagnostic reliability for adult patients from phase one of this field trial, using the Jan. 15, 1978, draft of *DSM-III*.

METHOD

Clinicians were invited to participate in the field trial through notices appearing in *Psychiatric News* and other mental health publications. All clinicians who agreed to complete the required work were accepted as participants, either as private practitioners or as groups of clinicians working within facilities. The clinicians were from all parts of the country, from Maine to Hawaii, and worked in both rural and urban settings. Over 80% identified their main professional activity as patient evaluation or care. The rest were distributed among administration (7%), teaching (7%), and research (3%). Only those clinicians who joined in groups participated in the reliability study.

Each clinician in this study was expected to participate with another clinician in at least two reliability evaluations. These two evaluations were to be done after each clinician had already used the *DSM-III* draft in evaluating at least 15 patients selected from his or her patient population as either consecutive admissions or "catch-as-catch-can" (an approximation of the ideal of random sampling). The reliability interviews, with only a few exceptions, were initial diagnostic evaluations before the beginning of treatment. Detailed instructions were given to the clinicians to avoid possible biases. For example, the clinicians were cautioned not to choose cases specifically because they presented no differential diagnostic problems and not to discuss a case before each clinician's independent completion of the diagnostic forms. Sim-

Received Dec. 11, 1978; revised March 8, 1979; accepted March 12, 1979.

Overall kappa for major classes, axis I		.78	.66
Overall kappa for personality disorders, axis II	60.6	.61	.54

[a]Percent of all subjects given diagnosis by at least one clinician. Because some subjects received diagnoses from two minor classes within a major class (e.g., a major affective disorder and a chronic minor affective disorder), the total percent of subjects in minor classes may exceed the percent of total subjects in the major class. Only in the case of substance use disorders was there an appreciable difference in percentages between the groups (joint=28.7%, test-retest=14.5%).

larly, participants were reminded that *DSM-III* was on trial, not them, and they should send in results even if they indicated poor agreement.

Both clinicians were to have access to the same material, such as case records, letters of referral, nursing notes, and family informants. If one clinician had such information (e.g., spoke to a family member), he or she was to inform the other clinician of the additional information, while at the same time avoiding communication of his or her diagnostic impression. Clinicians could either be present at the same evaluation interview (joint) or if this were inconvenient, separate evaluations could be done, as close together in time as possible (test-retest).

Each clinician recorded the results of his or her examination using the *DSM-III* multiaxial system. In this system personality disorders and specific developmental disorders are coded on axis II, and all other clinical psychiatric syndromes and conditions are recorded on axis I. The justification for separating the axis II disorders from the rest of the classification is to ensure that personality disorders and specific developmental disorders are not overlooked when attention is given to the axis I mental disorders, which frequently have more florid symptomatology. The use of the multiaxial system and the reliability of the nondiagnostic axes are described elsewhere (2).

RESULTS

Of the 365 clinicians participating in group settings and who see adult patients primarily, 274 participated in this reliability study. Two hundred and eighty-one adult patients (18 years and older) were evaluated. The ethnic-racial distribution of the patients (NIMH-recommended classification) was broken down as follows: white, not of hispanic origin (81%), hispanic (4%), black, not of hispanic origin (13%), and other (2%). The patients were evaluated in the following clinical settings: inpatient (33%), outpatient (34%), drug or alcohol service (10%), liaison service (6%), college mental health service (5%), and all other (12%). The inpatient evaluations were done in the following types of facilities: city or county psychiatric hospital (13%), state hospital (10%), private psychiatric hospital (47%), university-affiliated hospital (22%), and armed forces or VA hospital (9%).

Most of the clinicians evaluated 2 patients each; some evaluated 1, and a few evaluated several. Slightly more than half of the evaluations were done jointly.

The interrater reliability for the diagnostic classes that were represented in the patient sample is presented in table 1. Reliability is expressed using the kappa statistic, which indexes chance-corrected agreement (3). A high kappa (generally .7 and above) indicates

good agreement as to whether or not the patient has a disorder within that diagnostic class, even if there may be a disagreement about the specific disorder within the class. For example, diagnoses of paranoid schizophrenia and catatonic schizophrenia by two clinicians would be considered agreement on schizophrenia. The overall kappa for the major classes of axis I indicates the extent to which there is agreement across all diagnostic classes for all patients given an axis I diagnosis by at least one of the clinicians and is thus an overall index of diagnostic agreement.

DISCUSSION

For most of the classes, the reliability for both interview situations is quite good and, in general, is higher than that previously achieved using *DSM-I* and *DSM-II*. These results were so much better than we had expected that we wondered if our instructions for avoiding bias might have gone unheeded in many cases. However, the results of an anonymous questionnaire sent to all of the reliability participants indicated that there were only a few departures from the rules that might have inflated reliability; these included selection of a case because of an obvious diagnosis, changing a diagnosis after discovering the partner's diagnosis, or not sending in a case in which there was diagnostic disagreement. (It should be noted that studies of diagnostic reliability rarely consider the possibility of departure from protocol.)

It is particularly encouraging that the reliability for such categories as schizophrenia and major affective disorders is so high. Several important classes still have only fair reliability—schizoaffective disorder, chronic minor affective disorder, and personality disorder. In the final draft of *DSM-III*, schizoaffective disorder is redefined and will be included as one of the specific disorders within the class of "psychoses not elsewhere classified." The boundaries between chronic minor affective disorder and related disorders are being clarified, and we hope this will result in improved reliability. Although personality disorder as a class is more reliably judged than previously, how to further improve its reliability is not at all clear.

As expected, the reliabilities are higher when the interviews are done jointly. Although 40% of the test-retest interviews were done within one day of each other, almost half were done more than three days apart. Nevertheless, the drop in reliability for most of the classes is relatively small. Differences between reliabilities obtained under the two conditions may be due to different questions being asked by each interviewer as well as the patient's giving different responses to the same question asked at both interviews.

Several innovative features of *DSM-III* have undoubtedly contributed to the improved diagnostic reliability: changes in the classification itself (e.g., grouping all of the affective disorders together), the separation of axis I and axis II conditions, the systematic description of the various disorders, and the inclusion of diagnostic criteria. In future reports we will present the reliability of the individual diagnostic categories and the results of phase two of the field trial, which involves reliability interviews to assess the effect of changes made in the *DSM-III* classifications and in the diagnostic criteria.

DSM-III Field Trials: II. Initial Experience with the Multiaxial System

BY ROBERT L. SPITZER, M.D., AND JANET B.W. FORMAN, M.S.W.

The multiaxial system of DSM-III *includes nondiagnostic data that are valuable in understanding possible etiological factors and in treatment planning and prognosis. The authors describe the reliability of axis IV—severity of psychosocial stressors—and axis V—highest level of adaptive functioning in the past year—for 281 adult patients interviewed in phase one of the* DSM-III *field trials. The kappa coefficient of agreement for axis IV was .62 for joint interviews and .58 for separate interviews, which the authors consider at least fair. Reliability for axis V was quite good, .80 for joint interviews and .69 for separate interviews. Eighty-one percent of the participating clinicians judged the multiaxial system to be a useful addition to traditional diagnostic evaluation, although many indicated that they had difficulty quantifying severity of psychosocial stressors.*

ONE OF THE major innovative features of the draft version of the third edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-III*) is the provision of a multiaxial system for psychiatric evaluation. The multiaxial framework provides for the systematic evaluation of an individual's condition in terms of several variables, or axes, which are conceptualized and rated as quasi-independent of each other. The advantages of a multiaxial evaluation include comprehensiveness and the inclusion of nondiagnostic data that are valuable in understanding possible etiological factors and in treatment planning and prognosis. Furthermore, separating various aspects of the diagnostic information onto separate axes promotes higher interclinician diagnostic agreement.

Received Dec. 11, 1978; revised March 8, 1979; accepted March 12, 1979.

Dr. Spitzer is Chairman, American Psychiatric Association Task Force on Nomenclature and Statistics, and Chief, Biometrics Research Department, New York State Psychiatric Institute, 722 West 168th St., New York, N.Y. 10032, where Ms. Forman is Project Coordinator, *DSM-III* Field Trials, and Research Scientist, Biometrics Research Department.

This work was supported in part by National Institute of Mental Health Division of Biometry and Epidemiology contract 278-77-0022.

The authors wish to thank the field trial participants for their efforts and Dr. John Nee for his statistical assistance.

The basic rule in a multiaxial system is that for every case each axis is considered. For the system to be workable it must be restricted to a small number of axes, chosen on the basis of providing information of maximum clinical usefulness in the greatest number of cases. Several multiaxial systems for psychiatric evaluation have been proposed (1-3). The *DSM-III* multiaxial system was developed after reviewing these other systems and the experience of investigators using them.

In this paper we will describe the *DSM-III* multiaxial system and its use in phase one of the NIMH-sponsored field trials. Two questions will be addressed: What is the reliability of the nondiagnostic axes? and How do the users of the multiaxial system judge its usefulness?

THE MULTIAXIAL SYSTEM

Each individual is evaluated on each of the following diagnostic axes:

Axis I. Clinical psychiatric syndrome(s) and other conditions.

Axis II. Personality disorders and specific developmental disorders.

Axis III. Physical conditions.

Axes I and II comprise the entire classification of mental disorders as well as conditions not attributable to a mental disorder. The justification for separating the axis II disorders from the rest of the classification is to ensure that personality disorders and specific developmental disorders are not overlooked when attention is given to the axis I mental disorders, which frequently manifest more florid symptomatology.

Provision is made for indicating those instances in which there is no axis I diagnosis but there is an axis II disorder, and the reverse. Axis II may also be used to list prominent personality features not adequately subsumed by a personality disorder diagnosis, such as prominent compulsive traits.

Axis III permits the clinician to indicate any current physical disorder or condition outside of the mental disorders section of *ICD-9-CM* (4) that is potentially relevant to the understanding or management of the individual.

For special clinical, research, or teaching purposes, the following two nondiagnostic axes may be used:

Axis IV. Severity of psychosocial stressors.

0002-953X/79/07/0818/03/$00.40 © 1979 American Psychiatric Association

Axis V. Highest level of adaptive functioning in past year.

Axis IV permits the clinician to indicate 1) the specific psychosocial stressors that are judged to be significant contributors to the development or exacerbation of the current disorder and 2) a rating of the overall severity of stress that an "average" person with similar socioeconomic and cultural circumstances would experience. This judgment involves consideration of the amount of change in the individual's life due to the stressor, the degree to which the event is desired and under the individual's control, and the number of stressors. The individual's idiosyncratic vulnerability or reaction to the stressor should not influence the severity rating. The severity rating should reflect the summed effect of all the psychosocial stressors that are listed. A seven-point severity scale ranging from "none" to "catastrophic" is provided, with examples for both adults and children and adolescents. The specific psychosocial stressors are not coded.

Axis V permits the clinician to indicate his or her judgment of an individual's highest level of adaptive functioning during the past year. Adaptive functioning is a composite of three major areas: social relations, occupational functioning, and the use of leisure time. The clinician indicates the highest overall level of adaptive functioning that was characteristic of the individual for at least a few months during the past year, giving greater weight to the level of social relations because of its particularly high prognostic significance. A six-point scale ranging from "superior" to "grossly impaired" is provided, with examples for both adults and children and adolescents.

METHOD

Clinicians were invited to participate in the NIMH-sponsored field trial through notices appearing in *Psychiatric News* and other mental health publications. All of the clinicians who agreed to complete the required work were accepted as participants, either as private practitioners or as groups of clinicians working within facilities. The clinicians were from all parts of the country, from Maine to Hawaii, and worked in both rural and urban settings.

We have described elsewhere (5) the methodology used in the reliability study to ensure a representative sample of patients and to avoid bias, the distribution of patients among the clinical settings, and the ethnic-racial distribution.

Each participant in the field trial was expected to use the Jan. 15, 1978, draft of *DSM-III* to evaluate at least 20 patients selected as either consecutive admissions or "catch-as-catch-can," after which they were sent a lengthy questionnaire that included several questions about the multiaxial system. To insure candor in the replies, the questionnaire was anonymous. After each participant had completed at least 15 cases he or she was expected to complete 2 reliability evaluations with a colleague, either during a joint interview or separately, within no more than a few days. (Most of the clinicians evaluated 2 each, some only 1, and a stalwart few evaluated several patients.)

RESULTS

Of the 365 clinicians participating in group settings and who see adult patients primarily, 274 participated in this reliability study. Two hundred and eighty-one adult patients (18 years and older) were evaluated. Slightly more than half of the evaluations were done jointly.

The intraclass reliability coefficient for axis IV was .62 for cases evaluated in joint interviews (N=150) and .58 for evaluations made after separate interviews (N=131). For axis V the coefficients were .80 for joint interviews and .69 for separate interviews. The reliability of the judgment of the severity of psychosocial stressors is at least fair. The reliability of the judgment of the highest level of adaptive functioning is quite good. As expected, in both instances the reliability is better when the interviews are done jointly than when done separately.

Questionnaires were received from 271 field trial participants. The first question relevant to the use of the multiaxial system asked whether it was useful to divide the entire classification of mental disorders into axis I and axis II conditions. Sixty-eight percent responded yes and 10% responded no. (The proportion of clinicians responding "not sure" will not be reported for any item.)

Seventy-four percent reported that it was "useful to be able to note personality traits (as distinct from personality disorders) on axis II." Ten percent reported that it was not.

Since many field trial participants indicated in their critiques of *DSM-III* that they were dissatisfied with some aspect of axis IV, several mutually exclusive options were presented. Thirty percent favored changing the instructions so that the rating is purely descriptive of stressors that occurred before the current disorder, whether or not the clinician judges them to be significant contributors to the onset or exacerbation of the disorder. Ten percent favored eliminating axis IV on the grounds that "we do not yet know enough to measure stress in a way that would be useful clinically" and in actual practice this axis would not be used. Thirty-eight percent favored leaving axis IV as is and indicated that they found it "clinically useful in deciding a treatment approach and in evaluating prognosis" and that they would use it regularly in their diagnostic evaluations. Fourteen percent favored leaving axis IV as is even though they doubted that they would use it themselves but that "in some settings it would be useful information (e.g., for research)."

Only one question seemed necessary to assess axis V. Sixty-three percent judged it useful, and 10% did not. One question assessed the overall attitude toward

the multiaxial system: 81% agreed with the statement, "The *DSM-III* multiaxial system will be a useful addition to traditional psychiatric diagnosis," and 4% disagreed.

DISCUSSION

The limited reliability of the severity of psychosocial stressors aspect reflects the problems involved in quantifying this dimension. Many of the participants noted that they had difficulty in using the concept of the hypothetically "normal" individual as the baseline for judging the severity of the stressor. They often objected to the instruction to ignore the patient's idiosyncratic vulnerability in assessing severity of stressors. The solution to this problem is not at all clear; if one were to include the individual's vulnerability, the ratings would be more a reflection of individual psychopathology than of psychosocial stressors.

Other field trial participants took the opposite approach and objected to any etiological attribution to the stressors. They argued that the rating should merely be of stressors that occurred before the development of the illness, whether or not the clinician judged them to have any relationship to the onset or exacerbation of the illness. Although a large portion of the questionnaire respondents favored this approach, the majority seemed to favor leaving the instructions as they were. We are reluctant to change the instructions in the direction of pure description, despite its apparent advantages in objectivity. If the clinician were asked to consider events that he or she believed had no relationship to the onset or exacerbation of the disorder, the clinical usefulness of the information would seem to be extremely limited.

Because of the large number of negative comments about axis IV, we were surprised that so few wished to eliminate it from the multiaxial system.

Axis V was not only reliably judged but met with considerable approval. Several participants made valuable suggestions for modifying the examples in the scale to include more examples of high levels of adaptation in members of low social class.

Despite the greater demand placed on the clinician by the multiaxial system and the difficulties involved in the use of axis IV, the vast majority of the field trial participants apparently believe that the *DSM-III* multiaxial system is a useful addition to the traditional diagnostic evaluation. Future studies are necessary to determine the extent to which the multiaxial system and, in particular, axes IV and V will actually be used in clinical practice and their impact on patient care.

Massive Benzodiazepine Requirements During Acute Alcohol Withdrawal

BY ELAINE WOO, M.D., AND DAVID J. GREENBLATT, M.D.

Severe alcohol withdrawal developed in an abstinent chronic alcoholic man. Massive doses of benzodiazepines (2,335 mg of diazepam intravenously, 21,225 mg of oxazepam orally) achieved only marginal control of delirium and agitation. Analysis of multiple blood samples drawn during and after the withdrawal episode indicated, as expected, very high concentrations of diazepam and metabolites and of oxazepam. There was no evidence of an abnormal pharmacokinetic profile. Benzodiazepine resistance in withdrawing alcoholics probably reflects a receptor-site phenomenon rather than an abnormal drug disposition.

BENZODIAZEPINE DERIVATIVES, in particular chlordiazepoxide and diazepam, are extensively used in the treatment of the acute alcohol withdrawal syndrome (1, 2). The safety and effectiveness of benzodiazepines in acute alcohol withdrawal are well established, but doses greatly exceeding the usual therapeutic range are often required to produce an adequate clinical response. The reasons for these increased drug requirements are not known. The present report describes a case of acute alcohol withdrawal in which very large doses of oxazepam and diazepam were needed to control clinical manifestations.

CASE REPORT

A 33-year-old man was hospitalized following a grand mal seizure. The patient had a history of at least 3–4 years of heavy ethanol ingestion. He had been hospitalized two previous times for the alcohol withdrawal syndrome. In prior admissions hepatomegaly and ascites were noted, and micronodular cirrhosis was documented by percutaneous liver biopsy. Liver function tests were normal during periods of abstinence.

During the first day of hospitalization, the patient developed tremulousness and sinus tachycardia, but mental status remained normal. High-dose oxazepam therapy was begun, and the patient received 780 mg during the first 24 hours. Despite this, he rapidly developed severe agitation, hallucinations, and disorientation, consistent with the alcohol withdrawal syndrome.

Massive doses of oxazepam and diazepam were given over the next 7 days. A total of 2,335 mg of diazepam was given intravenously over 4 days. Bolus doses ranged from 10 to 100 mg, with a maximum of 270 mg given in three doses over 45 minutes. The maximum 24-hour dose of diazepam was 875 mg on the third hospital day. Oxazepam was given concurrently whenever oral intake was possible. Over 9 days, a total of 21,255 mg of oxazepam was given. Maximum single doses were 150 mg/hour, and a maximum 24-hour dose of 3,500 mg was administered with only minimal control of the withdrawal syndrome. There was no evidence of respiratory or cardiovascular depression, and only minimal sedation, attributable to any dose. Diazepam was discontinued on the fifth hospital day (point A, figure 1), and oxazepam was tapered and discontinued on the ninth day (point B, figure 1). Normal mental status had returned by the seventh day of hospitalization. The patient was subsequently discharged to a long-term treatment and rehabilitation facility.

METHOD

A venous blood sample was obtained prior to the initiation of benzodiazepine therapy and then at multiple points in time over the next 35 days. Plasma was separated and stored at −20°C until the time of assay. The patient's mental status was assessed at the time of blood sampling by observers having no knowledge of the drug concentrations. Plasma concentrations of diazepam and its three major metabolites (desmethyldiazepam, temazepam, and oxazepam) were determined by electron-capture gas-liquid chromatography (3–5).

RESULTS

Figure 1 shows plasma concentrations of the four active compounds over a 38-day period. High levels of oxazepam were rapidly achieved within the first 12 hours. The onset of delirium tremens coincided with a decrease in oxazepam levels due to a premature a-

FIGURE 1
Plasma Concentrations of Diazepam, Desmethyldiazepam, Oxazepam, and Temazepam During and After Benzodiazepine Therapy for Alcohol Withdrawal[a]

[a]Point A, termination of intravenous diazepam therapy (total dose: 2,335 g); point B, termination of oral oxazepam therapy (total dose: 21,255 g).

tempt to wean the patient off sedative medication. The maximum plasma concentration of oxazepam was 14.8 μg/ml on day 6, at which time the patient was severely disoriented and agitated.

High concentrations of diazepam were obtained within 12 hours of beginning therapy. The maximum level was 6.4 μg/ml achieved on day 3, but even these concentrations produced only transient improvement of the patient's severe agitation.

Desmethyldiazepam and temazepam, the two active diazepam metabolites, rapidly appeared in plasma, reaching maximum concentrations during the 6th day of hospitalization. Temazepam concentrations thereafter fell to undetectable levels by the 14th day; its apparent half-life of disappearance was 21 hours. Disappearance of diazepam and desmethyldiazepam was much less rapid. Both compounds were detectable 32 days after the last dose of diazepam. The apparent elimination half-life values for diazepam and desmethyldiazepam were 68 and 120 hours, respectively. Oxazepam levels fell sharply after termination of therapy on day 9, with an apparent disappearance half-life of 13 hours. Thereafter, relatively low concentrations of oxazepam remained present in plasma, probably consistent with that produced from endogenous metabolism of diazepam.

DISCUSSION

The present report describes a patient with severe alcohol withdrawal syndrome requiring massive doses of benzodiazepine derivatives. Despite the very large doses, adequate clinical control was barely achieved. Plasma concentrations of diazepam and oxazepam were 10- to 100-fold greater than those usually observed clinically, consistent with the large doses administered. Furthermore, biotransformation of diazepam to its pharmacologically active metabolites, as well as elimination of these compounds, appeared to

be relatively normal. Thus the patient's resistance to drug effects cannot be attributed to failure of drugs to reach the systemic circulation or to abnormalities of drug biotransformation or elimination. We cannot exclude the possibility that the compounds failed to reach their sites of action in the brain. This, however, seems unlikely, since benzodiazepines are highly lipophilic and readily penetrate the blood-brain barrier (6). During a previous admission, the patient experienced a similar clinical course and was treated with high doses of chlordiazepoxide. Analysis of cerebrospinal fluid (CSF) concentrations of chlordiazepoxide and metabolites at that time clearly indicated the presence of adequate levels of drug and metabolites in CSF.

A similar type of drug resistance or adaptation occurs following massive overdosage of diazepam in physically healthy individuals (5). The resistance of such patients to the action of benzodiazepine derivatives probably occurs at the cellular sites of drug action (7). The alcohol withdrawal syndrome itself, by poorly understood mechanisms, may also contribute to rendering such individuals relatively insensitive to the effects of central depressant compounds.

Further complicating the clinical problem of drug resistance during the early phase of treatment is the persistence of diazepam and its active metabolites for weeks after cessation of therapy. High residual levels of active compounds did not lead to untoward sequelae in our patient. However, prolonged obtundation has been reported following treatment of tetanus with high-dose diazepam (8, 9). The use of shorter-acting benzodiazepine derivatives having no active metabolites, such as oxazepam or lorazepam, might obviate such potential problems (10) and deserves further evaluation in the therapy of alcohol withdrawal.

Implications of Increased Dosage of Neuroleptic Medications During Psychotherapy

BY JOSEPH N. DIGIACOMO, M.D., AND RICHARD CORNFIELD, M.D.

Unrecognized emotional reactions on the part of the psychiatric trainee may result in the inappropriate use of medications. To illustrate the possibility that increases in medication dosages may be related to the psychiatric clinician's lack of control, the authors present three clinical examples and discuss the concept of countertransference. A model of supervision is described in which the supervisor, trainee, and patient meet to correct these therapeutic distortions and reduce the amount of medication required.

WITH INCREASED experience in assessing the effectiveness of neuroleptic medications, psychiatrists have gradually evolved general guidelines for a range of acceptable dosages in clinical practice. Some psychiatrists, however, continue to use neuroleptics in dosages substantially higher than those recommended in the clinical literature (1). The employment of high doses of neuroleptic medication merits careful evaluation. Although such practice is often therapeutically justifiable, it may also reflect patterns of lack of psychotherapeutic control in the doctor-patient interaction.

With the exception of a 1975 Group for the Advancement of Psychiatry study (2), psychiatry seems to have been curiously unattuned to subtle issues in the doctor-patient relationship that are obscured by such prescribing policies. Specifically, we are suggesting that excessive use of neuroleptic medication may indicate countertransference distortion on the part of the unwary psychiatrist and masquerade as effective rational treatment.

Marked changes in drug dosages should alert the supervisor of psychiatric residents and medical students to possible unrecognized emotional reactions on the part of the trainee to his or her patient. One pattern consists of gradual or rapid increase in medication, designed to control the patient's symptoms or behavior. The observable worsening of the disorder is initially assumed to be caused by the psychotic process for which the patient is being treated. If a therapeutic impasse is then reached, the trainee may label it "refractoriness" and increase the medication dosage, accentuating untoward side effects without concomitant control of the symptoms. If this sequence coincides with increasing distance in the therapeutic relationship, the pattern of medication usage may become a fertile area for the trainee to explore his unrecognized emotional response, or countertransference, to his patient. With a beginning therapist, the lack of countertransference control often seems most pronounced in those areas in which intense feelings or unpleasurable affects are generated. We will present examples that involve sexual feelings, hostility, and fear.

Received Jan. 6, 1978; revised April 14, 1978; accepted May 2, 1978.

CLINICAL EXAMPLES

Sexual-Erotic Feelings

A 25-year-old schizophrenic man was admitted to the hospital because of the acute onset of unruly behavior and bizarre ideation. He had been maintained on antipsychotic drugs and had remained out of the hospital for 2 years. His wife had become exhausted and resentful from caring for him. The patient responded dramatically to a female therapist, who used supportive psychotherapy and prescribed 600 mg/day of chlorpromazine. In 6 weeks the patient was participating in the ward community. However, at the end of the second month, his medication was abruptly increased to 1200 mg/day of chlorpromazine and 30 mg/day of trifluoperazine, and he required periods of restraint and seclusion.

Because of the high dosage of medications, a three-way interview was suggested with the trainee, patient, and supervisor. On entering the patient's seclusion room the supervisor observed that the patient was partially undressed and had many *Playboy* posters on his wall. A display at the foot of his bed depicted a stuffed turkey on a plate with the caption "I would like to stuff your turkey" (related to the Thanksgiving holiday). He appeared agitated yet somewhat jocular, with a rapid-fire, non-goal-oriented speech pattern. The supervisor inquired about the nature of the patient's relationship with his doctor and he replied that he was

0002-953X/79/07/0824/04/$00.45 © 1979 American Psychiatric Association

very attached to and dependent on her. It was soon evident from his associations that the patient was having intense sexual fantasies about his therapist. He talked about the problem of dealing with sexual feelings in the hospital. He felt secure with and close to his therapist at first but later noted a strong sexual attraction developing, with no means of letting off the sexual tension.

Later in supervision, the therapist said she had not noticed the posters. She revealed feelings of extreme protectiveness and solicitousness toward this patient and most of her patients. She said that about 2 weeks before this interview she began to feel mounting tension in the therapeutic relationship. It was at this time that she increased the dose of neuroleptics. After several discussions, both in individual and group supervision, the therapist was able to talk about her difficulty in dealing with a patient who made a strong sexual overture to her and saw that this problem was related to personal conflicts. Within a week she decreased the dosage of chlorpromazine to 600 mg/day, and the patient was again out of seclusion and participating in ward activities. In this situation the therapist, who was made anxious by the mobilization of her own sexual conflicts, retreated from the proper therapeutic approach and substituted psychoactive drugs in high dosages.

Hostile Feelings

A 50-year-old schizophrenic man was admitted to the hospital because of his progressive inability to cope with his family and to remain in the community. He spoke of various aches and pains in his body. Initially the patient had responded positively to 300 mg of thioridazine. His therapist was changed, and 4 days later the new therapist prescribed 800 mg/day of thioridazine and recommended an additional drug. Because of the apparent deterioration in the patient's condition, a supervisory three-way interview was arranged and the patient was asked about his feelings regarding his relationship with his new therapist. The patient was somewhat hesitant at first but with little encouragement began to speak in a very controlled way, periodically glancing at the student. The patient expressed concern that his current therapist had little regard or respect for him, that he was feeling "always put down," and that he was tense after their meetings. He said, "We always seem to end up disagreeing."

In group supervision following the interview, the student expressed surprise at what the patient had said. He felt, in retrospect, that he was "struggling with the patient for some reason or other." It was then noted that in the past his interpretations regarding this patient seemed "overheated," and he was asked if this case reminded him of something in his own life. The therapist admitted with annoyance that he could not tolerate the patient's constant complaints about his chest pain. He sensed that he was controlling the patient's verbal productions through frequent verbal interventions of his own in the therapy sessions. When asked why the complaints of chest pain produced this reaction, he responded that it was just something he felt strongly about.

Several days later he shared enthusiastically with the staff his insight that his father had had a myocardial infarction and had gone to the hospital, been treated, and returned home without ever showing a single sign of discomfort. He felt a deep sense of pride about his father's response to this painful, life-threatening situation and realized that it predisposed him to be critical of his patient's behavior. He was quick to point out that he still thought that his father reacted better to his heart attack than the patient did, but at least he now felt less antagonistic toward his patient. In a group discussion later, the therapist became aware that not only was he creating a very high standard for his patient but that he was trying to lead his own life by the same standards. He returned to his patient with considerably more comfort and enthusiasm. After the patient complained of being too sedated on 800 mg of thioridazine the dose was rapidly reduced to 200 mg/day.

Fearful Feelings

A 21-year-old acute schizophrenic man was admitted to the hospital in an extremely disorganized and hostile state, requiring both restraints and seclusion. The therapist prescribed 1200 mg/day of chlorpromazine and then added 40 mg/day of trifluoperazine, but little improvement in the patient's condition was noted. After 3 weeks, the staff was somewhat concerned about the escalating drug dosage and the continued use of leather restraints and spoke to the supervisor, who scheduled a three-way session.

During the interview, the therapist sat at a considerable distance from his patient. The patient became increasingly unruly and agitated as the therapist remained "frozen" in the background. The supervisor approached the patient, made physical contact with him through a handshake, and moved a chair close to the bedside. He initiated a friendly discussion, alluding to the fear that had been generated in the staff and patients by this patient's hostile demeanor. Although he was surprised to hear about the reaction, the patient admitted to being quite frightened himself. The supervisor attempted a demeanor of warmth and interest, which had clearly been lacking in the resident's interaction with the patient. A frank discussion of the nature of the relationship between the therapist and the patient ensued, and it became clear to the therapist that he had been unaware of the paralyzing fear that the patient generated in him. He realized that he tried to assuage his own fears by greater reliance on psychotropic medication as a chemical "restraint" of the patient.

In supervision, the therapist told about restrictions in his own life and fears of loss of control. The therapist gradually sensed that he had overcontrolled the patient's responses both with medication and with dis-

tancing maneuvers during the psychotherapy sessions. However, his subsequent responses appeared overcompensatory; he began to spend a great deal of time in close contact with the patient, frequently accompanying him on walks around the hospital grounds. He was never able to establish optimum distance and objectivity with this patient.

Peer group supervisory sessions in which the therapist became aware of his fears were not sufficient to help him deal with this patient or other intimidating patients. Attempts to desensitize his anxiety and increase his tolerance of aggressive behavior through psychodrama, observation of other trainees' work with similar patients, and direct observation of a senior staff member's management of such a patient were unsuccessful.

DISCUSSION

The interrelationship between pharmacotherapy and psychotherapy has raised many complicated issues (3–6). Recently, Docherty and associates (7) discussed the problem of "bimodal relatedness," involving the therapist's relationship to the patient as a diseased organ or as a disturbed person; they stress the need to continually resolve the tendency toward such polarization. The Group for the Advancement of Psychiatry in its 1975 publication (2) attempted to summarize studies of both treatment modalities in the major psychiatric disorders. The report discusses the possible beneficial effects of drugs on psychotherapy, such as facilitating the patient's accessibility to therapy by relief of the patient's symptoms, which enhances the ego functioning that is essential for participation in the therapy process. However, there is no documentation of the harmful effects of countertransference problems on proper clinical pharmacotherapy.

Sabshin and Eisen (8), several years after the introduction of neuroleptics in this country, showed that fluctuations in ward tension had a significant effect on the doses of tranquilizers used and suggested the need for careful studies related to prescribing practices and shifting levels of staff anxiety and discomfort.

Sarwer-Foner (5, 9, 10) emphasized the psychodynamics of prescribing practices in various settings. He stressed not only specific pharmacologic drug effects on the mental apparatus, such as dampening intensity of impulses, but also such factors in the total physician-patient relationship as the social setting, the patient's expectations of a drug's effect, the patient's transference to the therapist, and the physician's countertransference reactions (e.g., medication choice based on fear of interpersonal relatedness and a need for distance from a particular patient) (9).

In general, there is little documentation of the effects of stresses in psychotherapy on prescribing practices, particularly as manifested by sharp increments in medication dosage. The examples cited involve countertransference attitudes of the therapist, defined as emotional reactions to the patient resulting from unresolved unconscious conflicts in the therapist that impede effective therapy and lead to inappropriate use of neuroleptic medications.

Greenson (11) has discussed a variety of emotional reactions that may suggest lack of control. Among them are attitudes of love, hatred, pugnaciousness, and one-upmanship, as well as some subtle forms of countertransference such as rescue fantasies, unyielding good-naturedness and benevolence, protectiveness and motherliness, and feelings of boredom, coldness, and indifference. He mentioned the effect of "extraordinary experiences in the [therapist's] life [that] make him temporarily excessively susceptible to countertransference reactions as, for example, personal miseries, illness or death in his family, a pregnancy, the loss or suicide of a patient, etc."

There appears to be general knowledge of countertransference difficulties revealing themselves in either the failure to medicate the patient or the underutilization of medication (6). The dynamics of such situations may relate to the therapist's need to preserve an image of himself as a messianic healer who can fulfill all of the patient's needs and desires, thus assuring himself of his own ability to handle unresolved infantile fears and needs.

It seems equally important to consider the increased use of medication as an indication of a countertransference reaction. Such lack of control should always be suspected when a therapist is struggling to be helpful to the patient. This behavior results in a therapeutic step that often betrays the hidden conflict and usually proves to be nontherapeutic. To deal with such situations, particularly at a time of growing concern in the field of psychiatry over the morbidity associated with high doses of neuroleptics (12), we suggest that trainees and staff become sensitive to the issue of fluctuating doses of medication, particularly in those patients who were treated initially in an effective manner with modest doses.

The presence of delayed escalating doses can be an indication for an interview with the therapist, patient, and attending psychiatrist. This model of supervision requires careful thought and intervention, as it involves more than the usual problems inherent in a supervisor-trainee relationship. Particularly, countertransference needs on the part of the supervisor must be guarded against and the triadic interview must be delicately handled to avoid frightening the already struggling therapist. During the interview, the supervisor may take the initiative to clarify the interaction between the patient and therapist and identify affects that have developed which the patient and therapist have been unable to approach. The therapists are frequently able to use these encounters to assimilate areas of selective inattention through further direct and/or peer group supervision. Students and trainees, after overcoming defensive tendencies during the sometimes stressful interviews, often refer to these sessions as high points in their learning experience.

Relations Between Academic Departments of Psychiatry and Pharmaceutical Companies

BY MICHAEL JELLINEK, M.D., AND AARON LAZARE, M.D.

The financial pressures placed on academic departments of psychiatry make the offers of assistance from pharmaceutical companies very attractive. The authors provide a sequential three-step decision-making approach to help the academic physician and the psychiatry department address the ethical issues involved in any given interaction with a pharmaceutical company. They also provide examples of the application of these guidelines.

RECENT FINANCIAL CONSTRAINTS on departments of psychiatry require even more vigorous efforts to maintain high academic and service standards. Hospitals, reflecting institutional budget concerns, are developing administrative systems that emphasize cost containment and budgets based almost solely on income from patient services. Federal training grants have virtually disappeared, and third-party carriers have limited the definition of reimbursable services. As a result, funds for many departmental activities and resources, such as resident training, library facilities, guest lecturers, and research, have been severely restricted or eliminated. Departments have responded to these financial pressures by acquiring such new sources of revenue as contracting with community facilities and the Veterans Administration for resident time, sponsoring postgraduate courses, and engaging in various collaborative relationships with pharmaceutical companies.

The current extent of the interaction of academic physicians and psychiatry departments with pharmaceutical companies is remarkable in both number and complexity (see appendix 1). In one day the academic physician may use a pen embossed with a pharmaceutical company's name, write on note paper that has company advertising printed on it, carry company gifts of medical instruments in a company-donated bag, and

participate in company-sponsored research or teaching. The academic department may accept funds from a company for a guest speaker, use reference books donated by a company, carry out research funded by a company, or provide consultation or teaching time to a company.

The patient and the physician are often unaware of the interaction between department and pharmaceutical company because of the organizational complexity of the academic institution. For instance, a patient may not realize that a research project in which he or she has agreed to participate is serving, in part, the interests of a pharmaceutical company. A staff member may attend a lecture without knowing how much of the subject matter has been determined by a sponsoring drug company. The private practitioner, on the other hand, is in direct contact with the drug representative and invariably knows the nature of the interaction. Further, the private practitioner is not involved in research and teaching in his or her office.

At first glance it may appear that the variety of interactions between department and company simply enhance the position of both parties. In return for its financial investment the drug company may gain goodwill, the department's gratitude, an opportunity to educate and influence physicians as to the efficacy of its product, and a form of quasi-affiliation with the department, all with the understandable goals of enhancing its prestige, employee morale, and its competitive position. In return for its services the academic department is able to gain support for a wide range of patient care, education, and research programs.

A closer examination reveals that although the drug company's sales-oriented goals are straightforward and understandable, the psychiatry department's goals are more complex. For example, a department is entrusted by its larger institution (hospital and/or medical school) and by the public to discover truth (research) and to disseminate truth (teach). When a department appears to promote a particular drug by using company-printed stationery, by selecting company-designated research, or by sponsoring drug displays at lectures, the department faces the ethical dilemma of achieving its goals only by risking its public trust and academic purpose.

Academic departments are increasingly reliant on pharmaceutical companies through a wide variety of conceptually different interactions. It is important, therefore, that departments study the effects of these interactions on their broader goals and develop a system of ethical decision making. Traditional medical oaths or the more modern contractual models define basic ethical principles, but they provide no guidelines that are readily applicable for dealing with pharmaceutical companies or the complex ethical dilemmas in large medical institutions. We propose a sequential three-step decision-making approach that we hope will help the academic physician and the psychiatry department address the significant issues involved in any given interaction with a pharmaceutical company.

GUIDELINES FOR DECISION MAKING

Step 1. Review the specific details of the proposed activity in terms of basic ethical principles. In practice, these basic ethical principles would not permit unauthorized review of a patient's medical record (right of confidentiality), would not allow physicians to be diverted from the immediate and direct care of patients (physician's duty to the patient and pledge to do no harm), and would mandate that the patient be given the right to be fully informed and exercise free will in giving consent.

Step 2. Review the proposal in terms of its ultimate benefit to patient care. This guideline requires that there be significant benefit to the patient, to the department, to the physician, or to society in terms of increased knowledge (research or training) and/or increased quality and amount of patient care.

Step 3. If the proposal does not violate basic ethical principles and is a significant benefit, then consider potential risks. Risks include 1) diverting departmental or individual resources of time and energy to company interests, 2) raising patient concerns or even mistrust based on the patient's perception that the physician's judgment may be influenced by pharmaceutical companies' advertising or gifts, 3) the companies' use of their "affiliation" with the department to suggest an endorsement of their sales representative and their products in subsequent interactions with community physicians, and 4) contributing to the higher cost of medications without ultimate benefit to the patient.

EXAMPLES

1. Donations of funds for books. The anonymous donation of funds for books does not violate basic ethical principles (step 1), is of potential benefit to the department and indirectly to patient care (step 2), and has little risk of departmental or social corruption (step 3). The donation of specially designated books would carry certain risks if these books represented an unjustifiably large percentage of the available reading material in a small departmental library.

2. Company support for guest speakers. Support for speakers is a more complex problem. In general, funding speakers violates no basic ethical principles (step 1). However, the benefits are limited if the speaker or topic is circumscribed or biased on the basis of such company guidelines as a speaker's bureau or support limited to specific topics (step 2). The risks of diversion of departmental interest as well as departmental endorsement are variable as well, depending on the setting of the lecture (special lecture versus grand rounds, for example) and whether there is publicized sponsorship or active sales promotion associated with the lecture (step 3).

3. Stationery or memo paper with company advertising. In this example the benefit to the department is purely financial, i.e., a relatively minor administrative

saving (step 2). The risks include subliminally influencing physician prescribing patterns (choice of drug and use of trade name) and arousing patient concern or mistrust because the physician is identified on an advertising handout rather than on departmental or individual letterhead, memo sheets, or blank paper (step 3).

4. Outright gifts. Personal gifts such as lunches are without direct or indirect benefit to patient care (step 2). There are several risks in gifts, including influencing physicians by considerations other than what is best for the patient, blurring the boundaries between company and physician (step 3), and increasing the price of medicine without ultimate benefit to patient care.

5. Training pharmaceutical personnel. The training of pharmaceutical personnel by direct patient contact violates the basic ethical principle of confidentiality (step 1). Even when teaching is conducted without patient contact, the academic department risks violating the public trust when the company personnel attempt to use their "teaching affiliation" to enhance sales promotion (step 3).

CONCLUSIONS

The significant financial pressures on academic departments make pharmaceutical company offers very attractive and may easily divert a department's or a physician's attention away from making judgments about the most valuable use of time and the broader ethical implications of eroding the integrity of a department or teaching position. Conceptually, our guidelines on relations with pharmaceutical companies suggest that the academic department is generally bound by the same basic ethical principles as are its individual physician members and, further, that departmental activities be guided by ethical principles that acknowledge the department's societal position, role, and concomitant obligations.

APPENDIX 1
Examples of Pharmaceutical Company Support to Academic Departments of Psychiatry

GIFTS
- Pens (with or without advertising)
- Memo pads and stationery (with or without advertising)
- Medical instruments (with or without advertising)
- Reprints (general reviews or sales promotional)
- Textbooks
- Monographs (general reviews or sales promotional)
- Meals
- Drug samples for the physician's personal use, use for patients, or charitable use

SPEAKERS
- Academic conference of general topics (with or without acknowledging sponsorship)
- Company-approved speakers for specific topics
- Directly promotional speakers for specific drugs

RESEARCH
- Anonymous general support
- Support of drug evaluation research
- Research design based on sales promotional criteria

CONSULTATION TO THE COMPANY
- Company executive training without patient contact
- Company executive training with patient contact
- Sales promotion (with or without funds)
- Product improvement

A Clinical Note on Hysterical Psychosis

BY JESSE O. CAVENAR, JR., M.D., JOHN L. SULLIVAN, M.D., AND ALLAN A. MALTBIE, M.D.

The authors review the concept of hysterical psychosis and its reported psychodynamics. They suggest a psychodynamic issue that apparently has not been previously reported, namely, emotions engendered by an overt sexual advance or rage and disappointment over a lack of a sexual advance. This finding can be most helpful in distinguishing a case of hysterical psychosis from an acute schizophrenic episode.

MOST CLINICIANS AGREE that there is an entity best described as a hysterical psychosis that is distinctly different from an acute schizophrenic episode. Hysterical psychosis usually has a sudden and dramatic onset and may be manifested by hallucinations, delusions, depersonalization, derealization, and bizarre behavior. The hallucinations may be visual instead of auditory. The affect is not flat or blunted as may be seen in schizophrenic psychosis; instead, the affect may be effervescent and expansive. If a thought disorder is present, it does not resemble the looseness of associations seen in schizophrenia. Brill (1) stated, "The thought disorders in hysterical psychosis, even though characterized at times by delusions and hallucinations, are more like the simple distortions of reality seen in the very angry or fearful child, which disappear when emotional control is achieved" (p. 1066).

The acute psychosis may last from a matter of hours to several weeks. Once the psychosis has run its course, there are no residual effects; no chronic disability exists.

Hysterical psychosis occurs most commonly in persons (usually women) who are best described as having hysterical personalities. This personality type is suggested by a person who is self-centered, vain, dramatic, seductive, suggestible, emotionally labile and excitable, attention-seeking, and dependent. The person's moods tend to be shallow and superficial, and the thinking pattern is directed and controlled by the prevailing mood. These people tend to react to an affect-laden situation by becoming distraught; as the anxiety mounts, the person becomes overwhelmed and unable to mobilize an integrated pattern of behavior. At the extreme, this breakdown in functioning leads to a hysterical psychosis.

The dynamic events leading to decompensation in psychosis are more obscure. Hirsch and Hollender (2) have suggested only that a profoundly upsetting event or circumstance leads to decompensation. Mayer-Gross (3) felt that the psychosis develops with an emotional loss, an affective trauma, or a deprivation of support and home. Astrup and associates (4) suggested that hysterical psychosis is precipitated by fairly easily recognized exogenous factors. However, they did not suggest what these factors are.

Langness (5) has described the dynamics of hysterical psychosis in the Bena Bena tribe of New Guinea. In the examples given, it appears that the psychosis served as a discharge for aggressive impulses that could not be released in a socially acceptable manner without the psychosis.

Martin (6) has described the dynamics of women who have developed hysterical psychosis as a result of marital difficulty. He believed that these women have symbiotic attachments to their husbands and that their marriages are founded on hate instead of love. Yet these women have marked unresolved separation anxiety that ties them to their husbands, who are hated need-satisfying objects. Martin suggested that the women show oral, narcissistic character structures with primitive symbiotic object relationships and that they become psychotic when their life situation becomes intolerable. A short-lived hysterical psychosis provides the needed escape from the intolerable situation.

In the meager literature on hysterical psychosis, various dynamics have been proposed as leading to psychotic decompensation. The purpose of this report is to suggest that, in our contemporary society, there is a common dynamic factor leading to hysterical psychosis which has not to our knowledge been previously reported. This factor has been present in every case of hysterical psychosis that we have seen. We believe it has direct clinical importance because of the occasional difficulty in distinguishing a hysterical psychosis from an acute schizophrenic episode. If this dynamic issue can be ascertained, it clearly directs the physician's thinking toward a hysterical psychosis. Since the treatment and prognosis of a hysterical psychosis and a schizophrenic disorder may be quite dif-

ferent, the presence of this dynamic issue has paramount clinical importance.

The following case reports are illustrative of our experience.

CASE REPORTS

Case 1. A 21-year-old single woman was seen for emergency psychiatric evaluation because of the acute onset of auditory and visual hallucinations, bizarre behavior, and a dazed state. These symptoms had been present for 5 days and were worsening.

The mental status examination revealed a young woman who appeared dazed and bewildered. There was a rhythmic movement disorder of her right hand, and her eyes were fixed in the upward field of gaze. She did not appear depressed and denied depressive symptoms. She admitted to auditory hallucinations of her father's voice and had visions of her father reading the Bible to her. All of her conversation seemed to concern the father.

The patient was admitted to the inpatient unit because of the obvious psychosis and extreme regression. After a short period of observation, a psychiatrist asked the patient to tell him about her sexual feelings concerning her father. The rhythmic motion of the right hand immediately stopped, the upward gaze ceased and eye contact was established, and she began to talk in a coherent and logical manner. She revealed that her father had seemed to have "unusual" feelings about her since she was an adolescent. She had gone into military service to get away from home and particularly her father. Upon her discharge from military service and return home, her father commented on how much she had grown and casually asked her to remove her clothes. She complied; the psychosis began soon afterward.

After the patient openly discussed her sexual feelings for her father and her father's sexual feelings for her, the psychiatrist reminded her that people have many different feelings about many different things and that just because feelings may be present, it is not necessary to act on the feelings. After the one psychotherapy session, the patient's hysterical psychosis cleared completely in 24 hours; she was then transferred to an open ward.

Case 2. A 23-year-old single woman was admitted to a psychiatric facility on an emergency basis because of the sudden onset of psychotic behavior. She had been with a date in a nightclub when she suddenly stood up and screamed that she was being raped and began to throw various objects at patrons in the club. The police were called, and she was brought in this violent state for admission.

The mental status examination revealed an attractive young woman who talked about being raped in view of everybody at the nightclub. She commented that she would probably need to be hospitalized for 9 months and reminded the psychiatrist that this was the length of a pregnancy. She was seductive and coy throughout the interview; her affect was volatile and ranged from rage to flirtatiousness.

The patient improved rapidly after hospitalization. Subsequent interviews revealed that her date was a man whom she had dated for several months; she was aware of strong sexual feelings for him and was angry that he was not making sexual advances toward her.

Case 3. A 24-year-old married woman was found unconscious in her home and was taken to a community hospital where she was believed to have had a cerebral hemorrhage. She was transferred via helicopter to a large medical center for neurosurgical intervention; prior to transfer a brachial cutdown had been done without anesthesia.

Neurological examination at the medical center revealed no localizing signs or nuchal rigidity. The patient appeared to be comatose but did respond to deep pain. Psychiatric consultation was requested.

The mental status examination revealed a very attractive young woman who was comatose and dressed in "baby doll" attire. The psychiatrist sat by her examining table and, after calling her by name, began to talk to her about how frightened and anxious she must be. After a few minutes, the patient opened her eyes and looked around in a dazed manner; slowly she began to ask where she was and how she arrived there. The intravenous tubing was removed and the cutdown site sutured.

As the patient became more alert and responsive, she revealed that her husband was a military officer who was stationed overseas. She had entertained sexual fantasies about another man for several months; she had gone unaccompanied to the officers' club the previous evening and "accidentally" met this man. He had made an overt sexual proposition; she had no memory of the events from the time of the proposition until she awoke in the emergency room. Subsequent inquiry revealed that she had been acting in an irrational manner and talking strangely before leaving the officers' club the previous evening.

Case 4. A 30-year-old married woman was brought for psychiatric evaluation because of bizarre behavior of 48 hours' duration. During the mental status examination she looked about the room in a dazed, bewildered manner and responded to questions by darting her tongue in and out of her mouth without making a sound.

Family members who accompanied her said that she had attempted to wrap herself around a utility pole the previous evening. They suggested that she had been "hypnotized by a snake." A salesman known to the patient had called at the home she shared with another woman. The salesman and the other woman had sexual intercourse in a nearby room, and the patient could hear various noises. Later, the woman inquired about the travel bag the salesman had, and he told them that it contained his pet snake. At the women's insistence, he unzipped the bag and the snake crawled out. The patient commented that it was "the biggest, most beautiful snake" she had ever seen; she was immediately "hypnotized" and had displayed the bizarre behavior ever since.

The psychiatrist, who believed the woman had a hysterical psychosis, explained to her clearly that she was hypnotized by the snake but that he had medication more powerful than the snake's hypnotic power. With great inspiration and ceremony, he explained that she would be well before the medication reached her stomach. He gave her a colorful pill, and she suddenly recovered. The family members felt she had returned to her usual level of functioning.

The patient was seen for two follow-up visits and remained well. She was aware of intense sexual feelings for the salesman and was able to verbalize the conflict about her feelings.

DISCUSSION

In each of the cases reported, either a sexual advance was made to the patient or the patient was angry

because a sexual advance had not been made. Hysterical persons tend to sexualize all encounters and human relationships but are frequently in conflict about their own sexuality, as manifested by the fact that many hysterical women are nonorgasmic. The internal conflicts are tremendous. On the one hand, the woman wants to accept the sexual suggestion; on the other, she feels intense anxiety and guilt because of the desire to accept. One escape for the conflicted person overwhelmed by intense feelings is to regress and experience a psychosis.

Other women, such as the one in case 2, will become angry when a desired person does not make a sexual advance. To repair the narcissistic injury of not being sexually pursued, they may resort to pseudologia fantastica, or a wish-fulfilling delusion. This may reach such intensity that regression and psychosis rapidly follow.

We have found that in suspected cases of hysterical psychosis, it is important to inquire whether a sexual advance was made shortly before the onset of the psychosis. If no sexual advance was made, it is important to try to establish whether the woman felt that an advance should have been made. This information can be most useful in establishing a correct diagnosis of hysterical psychosis.

It should be recognized that hysterical psychosis is not limited to persons with hysterical personality. In patients with other personality types, the precipitant of a hysterical psychosis may be emotions of a nonsexual nature. We believe that our findings apply to those persons with hysterical personality organization.

Organic Personality Disturbance: A Case of Apparent Atypical Cyclic Affective Disorder

BY CARLA HELLEKSON, M.D., ROBERT BUCKLAND, M.D., AND TREVOR PRICE, M.D.

The authors present the case report of a 19-year-old woman that contains several important points in the diagnosis and management of organic personality disturbance associated with temporal lobe epilepsy. The behavioral changes may antedate the onset of the clinical seizure. The diagnosis of complex partial seizures is a clinical diagnosis in which surface EEGs may repeatedly not demonstrate focal activity. Carbamazepine can have important psychotropic effects, in addition to its well-established anticonvulsant effects, and it may be particularly indicated if a lithium-resistant bipolar affective disorder is a differential diagnostic possibility.

A RENEWED INTEREST in the psychiatric aspects of temporal lobe epilepsy, with Waxman and Geschwind's description of the interictal personality syndrome (1) and work on the characteristics of interictal behavior in temporal lobe epilepsy by Bear and Fedio (2) and Blumer and Benson (3, 4), has led to the inclusion of organic personality disturbance in the proposed *DSM-III* classification of organic mental disorders. The following case presents several unusual features that are necessary to bear in mind in order to correctly diagnose and effectively manage this disorder.

CASE REPORT

Ms. A, a 19-year-old college student, had apparently been well adjusted until August 1976, when she rather suddenly became irritable, preoccupied, slept less, and by her own report, "wasn't aware . . . like in a fog or in a dream." In addition, she began talking about being evil and worthless, and on one occasion while at a wedding she blurted out the words, "I almost committed suicide." She said these words "popped into my head." She said of the wedding, "It was like a religious experience."

The patient's parents described her as alternating between "highs and lows." For several days she would be friendly and talkative and then for several days she was irritable, withdrawn, self-deprecatory, and preoccupied with religion and the devil. Treatment for a presumed depression was begun with desipramine hydrochloride, 50 mg three times a day, without significant improvement. Four months after her behavioral changes had first been noted, she experienced her first generalized tonic-clonic seizure. Subsequently she was admitted to our medical center from a local hospital with a chief complaint of, "I've been mean." She had gained several pounds and was occasionally bothered by insomnia. There was no hypergraphia, and her sexual interests were limited. She had no history of head trauma, febrile seizures, or prior psychiatric disturbances. Family history revealed the suicide of her brother when she was 5 years old and suicide of a maternal aunt.

Ms. A was a tall, athletic woman who was hyperactive, pacing, and combative when approached. Her speech was pressured but coherent. Her mood was irritable, and her affect was detached and suspicious. Her thought content centered on self-deprecatory comments such as, "I need to be locked up because I did something wrong—I lost my judgment." No hallucinations were noted, but she made delusional comments such as, "I'm clinically dead now; no brain waves, no blood pressure, no heart." Illusions were not uncommon, i.e., in speaking of the nearby church bells, she said, "I remember when I heard bells ringing in the middle of the night; I thought it was Judgment Day." Her orientation was intact. The findings from a physical examination, including a detailed neurological examination, neuropsychological testing, laboratory work with metabolic screen, skull films, computerized tomographic scan, and lumbar puncture were within normal limits. Two EEGs done on admission, the second with nasopharyngeal leads, were slightly abnormal due to some slowing of the background rhythm with diffuse excess of fast and slow frequencies; no consistent focal features were observed.

Over the next 8 months spanning several admissions, the patient's cyclic pattern of "highs and lows" continued with the periodicity progressively shortening from 6 to 2 weeks. During her "lows" she was withdrawn, preoccupied, and occasionally angry, with a driven verbal stream of guilty self-condemnation and religious concern. In retrospect, she described these times as, "I didn't know where I was; it didn't seem real. I woke up and thought I was in Hell or something." Once, while at home, she attempted suicide by wrist slashing and drowning. During her "high" periods she was friendly, talkative, even socially intrusive, with many changes of clothing in a day and flamboyant use of makeup. For short periods in between these extremes, she was a warm and cooperative young woman interested in athletics and school. Extended trials of lithium carbonate in dosages up to 1800 mg/day, with blood levels of 1.2 to 1.4 mEq/liter, and amitriptyline in dosages up to 300 mg at bedtime

led to no improvement. Imipramine in dosages up to 200 mg at bedtime was also ineffective. A trial of perphenazine, 64 mg/day, did not help.

In June 1977 the patient experienced a second generalized seizure, and treatment with phenytoin, 300 mg daily, was started. The seizure was thought to have been related to high-dose tricyclic antidepressants. No further seizure activity was noted until the evening of July 22, 1977, when she walked up to the nursing station, appeared detached, and automatically stuffed several cellophane-wrapped sour balls into her mouth. She was led back to her room, where a generalized tonic-clonic seizure ensued. She denied premonitory sensations or olfactory/gustatory aura. The level of phenytoin was 15 mg/liter. An EEG with nasopharyngeal leads, the fifth since the onset of her symptoms, was slightly abnormal, with no lateralization of spike activity. The above episode was considered to be a complex partial seizure that generalized. One week after the institution of carbamazepine, 400 mg daily, her behavior stabilized dramatically. She was discharged in September 1977 on 300 mg of phenytoin and 400 mg of carbamazepine daily.

In the 16 months since discharge she has continued to report stabilized mood and has returned to her excellent level of premorbid functioning. This remission of symptoms has continued with carbamazepine alone since the discontinuation of phenytoin 5 months ago. No further seizure activity has been noted.

DISCUSSION

This case illustrates three important points in the diagnosis and management of *DSM-III*'s organic personality disturbance secondary to temporal lobe epilepsy. First, the behavior changes may antedate the onset of the clinical seizure disorder. Second, the diagnosis of complex partial seizures is a clinical diagnosis in which surface EEGs may repeatedly not demonstrate focal activity. Third, carbamazepine can have important psychotropic effects in addition to its well-established anticonvulsant properties when used in the management of patients with behavioral abnormalities associated with complex partial seizures.

The behavior changes described above began abruptly 4 months before the onset of generalized seizures, with periodic fluctuations between highs and lows. Although behavior changes antedating seizures have been reported (4), most accounts, including Slater and Beard's study (5), have described the slow development of the characteristic traits in the years after the onset of seizures. In our patient only three seizures occurred during the 12-month period of behavioral disturbance. This is in keeping with the trend suggested in Flor-Henry's retrospective study (6), in which the periodic or manic-depressive manifestations of temporal lobe epilepsy were more likely to be associated with infrequent generalized seizures than the schizophrenic-like psychoses.

Although organic personality disturbance was entertained in the differential diagnosis from the outset, the patient's disordered behavior was prematurely diagnosed as either schizo-affective disease or bipolar affective disorder with atypical features because of its superficial similarity to these functional disorders. The diagnosis was further delayed by the appearance of generalized seizures, which were thought to represent idiopathic epilepsy iatrogenically unmasked by high doses of tricyclic antidepressants and neuroleptics. During the patient's 12-month clinical course, she underwent extensive medical and neuropsychological evaluations, including five nonspecific EEGs (two with nasopharyngeal leads). Multiple adequate but unsuccessful clinical trials of lithium carbonate, antipsychotics, and tricyclic antidepressants, alone and in various combinations, and phenytoin were unsuccessful.

The probable diagnosis of temporal lobe epilepsy with interictal behavioral disturbances became apparent only with the nurses' observation of automatic, stereotyped behavior preceding the third generalized seizure. Based on these observations, carbamazepine was started, with dramatic and immediate improvement in the behavioral disorder that had continued over the subsequent 16 months of follow-up. This case emphasizes that the diagnosis of temporal lobe epilepsy and its related organic personality disturbance is a clinical diagnosis based on history and course. Multiple EEGs may fail to reveal specific abnormalities. Blumer (3) has outlined excellent guidelines for diagnosis of this disease.

The role of carbamazepine as an effective anticonvulsant in complex partial seizures is well accepted, while controversy continues concerning its possible behavioral effects (7). This case demonstrates a striking behavioral response, with stabilization of affective swings, modulation of maladaptive behaviors, and a return to the excellent premorbid level of functioning. It cannot be definitively determined whether this represents a response to carbamazepine of an atypical bipolar mood disorder that is lithium resistant (8, 9) or of temporal lobe epilepsy with an associated organic personality disturbance; however, the latter seems more likely.

What appears to be most important clinically is the fact that an earlier trial with carbamazepine was not considered. In retrospect, clinical features that might have suggested this are worth emphasizing. They include 1) the sudden onset of episodic and fluctuating behavioral symptoms, particularly if associated with a seizure disorder and a good premorbid history; 2) the nonresponse of a presumed cyclic mood disorder to lithium carbonate; and 3) symptoms specifically suggestive of temporal lobe epilepsy, such as feelings of unreality, alternating periods of appropriate interpersonal relating and social withdrawal, driven speech, forced thoughts, and ideational viscosity in the form of persevering religious and self-deprecatory preoccupations.

In conclusion, a clinical trial of carbamazepine may well be indicated when the symptoms of an organic personality disturbance are present and temporal lobe epilepsy is a diagnostic consideration, even in the absence of definite complex partial seizures or a diagnos-

tic EEG, particularly if lithium-resistant bipolar affective disorder is a differential diagnostic possibility.

CLINICAL AND RESEARCH REPORTS

This section contains 1) new research findings, including preliminary data from pilot studies, either clinical or laboratory; 2) worthwhile replication studies; 3) case reports that describe a truly new syndrome or cast new light on established ones; and 4) case reports that indicate a new therapeutic procedure of potential value or call attention to adverse effects of drugs or previously unreported complications of therapeutic interventions. Program descriptions and literature reviews cannot be printed in this section. Criteria for format are listed in "Information for Contributors" in each issue; papers that do not adhere to these criteria will be returned to the author.

Effects of Lithium Therapy on MAO in Manic-Depressive Illness

BY WADE H. BERRETTINI, M.D., PH.D., WOLFGANG H. VOGEL, PH.D., AND ROBIN K. LADMAN

Several investigators have evaluated platelet monoamine oxidase (MAO) in bipolar affective illness (1–5). Three of these reports indicated that platelet MAO activity is significantly lower in patients with bipolar illness than in control subjects (1–3). However, two other reports indicated increased platelet MAO activity in manic-depression (4, 5). A study of electrophoretic patterns of platelet MAO revealed no differences between manic-depressive and control subjects (6). The origins of these discrepant results are unclear. Investigators on both sides of this issue have used very similar radioenzymatic assays with the same substrate (tryptamine) and have based the specific activity on platelet protein (1–3, 5). Of course, differences in control and subject populations, which could result from the use of different diagnostic criteria, may account for the conflicting results. Another possibility is that bipolar affective illness may be a heterogeneous disorder with no common genetic factor by which abnormal platelet MAO activity might be determined.

This work was supported by Alcohol, Drug Abuse, and Mental Health Administration grant MH-31156 from the National Institute of Mental Health.

All of the existing studies of platelet MAO in bipolar affective illness have used substrates of questionable physiologic importance, such as benzylamine (4, 5) and tryptamine (1–5). These studies are limited because platelet MAO activity was measured at one substrate concentration, which provides little kinetic information.

Previous work in our laboratory indicates that platelet MAO is kinetically different in chronic schizophrenics and controls (7). This kinetic difference is characterized by a decreased maximal velocity (V_{max}) and Michaelis constant (K_m). This result is consistent with uncompetitive inhibition. We decided to determine whether a kinetic study of platelet MAO in manic-depressive illness would yield similar kinetic results, i.e., decreased V_{max} and decreased K_m. If similar kinetic results are obtained in manic-depressive illness, it would be less likely that the finding in schizophrenia is related specifically to that disease in a genetic or causal manner, particularly in view of the apparent lack of common genetic factors in schizophrenia and affective disorders (3).

We decided also to determine the kinetic effect of lithium treatment on platelet MAO among individuals with manic-depressive illness. Our interest in this study stems from two sources. It has been reported that lithium treatment increases platelet MAO activity in vivo but that addition of lithium carbonate to platelet preparations in vitro had no effect (8). Unfortunately, this study provided no control platelet MAO values with which one might compare the values from the manic-depressive subjects. In addition, Sullivan and associates (2) have reported that normal platelet MAO activity in a bipolar patient is predictive of good response to lithium treatment (2). They found that lithium responders as a group had normal MAO activity,

[a] V_{max} is expressed in nanomoles of dopamine per milligram of protein per hour.

while nonresponders had significantly less MAO activity than either the responders or the control group. This study indicates some degree of heterogeneity among individuals with bipolar affective disorders.

Method

Patients selected for this study were drawn from two acute care inpatient units at Thomas Jefferson University Hospital. All patients except numbers 4 and 8 were admitted for a manic exacerbation (see table 1), and all had been hospitalized at least once for depression and once for mania. None of the patients had taken lithium for at least 1 month before hospitalization. All patients except one (number 4) were treated with antipsychotic medication throughout the first 2 weeks of hospitalization. The duration of illness, defined as the number of years since the initial hospitalization, ranged from 2 to 32 years. All patients were free of other major illnesses and had normal complete blood counts, including platelet estimates. Informed consent was obtained from controls and patients. Baseline blood samples were obtained from all patients before they started lithium therapy. Thereafter blood samples were obtained periodically (at the same time as blood lithium samples were drawn) at least 10 hours after the last lithium dose. All patients satisfied the Research Diagnostic Criteria (9) for bipolar affective disorder.

The details of platelet MAO enzyme preparation and assay are described in full elsewhere (10). Controls were unit staff and laboratory personnel who were drug-free and had no personal or family history of psychiatric illness.

Results

The results (table 1) show that V_{max} and K_m did not differ significantly between manic-depressive patients and controls. Further, treatment with lithium did not significantly alter V_{max} or K_m values among these patients.

Discussion

In terms of platelet MAO activity, manic-depressive patients appear to be a very heterogeneous group. In this small series, several patients had high activity and 2 had rather low activity; the rest fell within 1.5 SD of

the mean activity for the control group. It seems clear that there is a subgroup of patients with very high activity. In our series, such patients were older women, but it is unlikely that this fact alone can account for this result. Several older women in our control group had normal platelet MAO activity. We were unable to determine any clinical measure that separates the high-MAO subgroup from the other subjects.

Our finding that lithium therapy does not significantly affect platelet MAO contrasts with the report of Bockar and associates, who reported increased platelet MAO activity during lithium treatment (8). There appeared to be very little variation in V_{max} values over a wide range of lithium levels, with the exception of patient 1, who showed a rather large fluctuation in platelet MAO activity. The patients, regardless of pretreatment platelet MAO activity, retained essentially the same activity during several weeks when therapeutic lithium plasma levels were maintained.

The previous report of increased platelet MAO activity during lithium treatment (8) is provocative because it provides an explanation of the efficacy of lithium in mania that agrees with the catecholamine hypothesis of affective disorders. An accumulation of catecholamines, causing mania, would be reversed by lithium via its effect on MAO. Unfortunately, we have been unable to duplicate these results.

These results do offer partial support to reports of both increased (4, 5) and decreased (1–3) platelet MAO activity in manic-depressive illness. In our series, there are patients with both high and low platelet MAO activity. Certainly, differences in patient populations, diagnostic criteria and enzymatic procedures could account for these results. It does seem that our group of patients may be more heterogeneous, at least biochemically, than other groups.

Perhaps the most interesting finding in this study is the subgroup of patients with high platelet MAO activity. The identification of biochemically (and/or genetically) distinct subgroups in major psychiatric illnesses would almost certainly lead to a more comprehensive, complex, and accurate conception of these diagnostic categories.

Micrographia and Akinesia

BY DANIEL R. SHACKMAN, M.D., THEODORE VAN PUTTEN, M.D., AND PHILIP R.A. MAY, M.D.

Part of the art of antipsychotic drug therapy is distinguishing side effects from the vicissitudes of schizophrenia. In particular, mild akinesia is evident primarily as a behavioral state of diminished spontaneity characterized by few gestures, unspontaneous speech, apathy, and difficulty initiating usual activities (1). Akinesia is insidious and, particularly when superimposed on chronic schizophrenia, can worsen such negative symptoms as blunting of affect and emotional withdrawal (2). The problem is that akinesia is easily confused with depression, demoralization, or the negative symptoms of schizophrenia, and even experts at times cannot distinguish between a depressive mood shift and an antipsychotic-induced akinesia (3). What is needed is some reliable and readily observable clinical correlate of mild akinesia.

Constriction of handwriting (micrographia) has been reported to be a sensitive indicator of extrapyramidal involvement (4–6). According to Haase and Janssen (4) and Angus and Simpson (6), constriction of handwriting precedes observable drug-induced parkinsonism. This notion has gained some measure of acceptance but has seldom been rigorously examined. We conducted the study reported in this paper to determine whether constriction of handwriting is a reliable correlate of mild akinesia.

Method

Twenty-four newly admitted patients who met Feighner and associates' (7) criteria for schizophrenia received treatment with an antipsychotic drug (most commonly thiothixene) after a drug-free observation period of 1–21 days. The average duration of drug treatment was 43 days (SD=16.5 days).

The control group consisted of 7 nurses and secretaries who had no knowledge of the protocol.

Handwriting samples were collected at 9:00 a.m. before treatment started, and weekly thereafter, by a technician who was blind to the akinesia ratings. All subjects were asked to copy the nursery rhyme "Mary Had a Little Lamb" from a typed card three times, on unlined translucent paper, with the same ballpoint pen. (This procedure follows the technique used by Haase and Janssen [4].)

Three measures of handwriting were chosen for study: average word length (total length of lines divided by number of words), average area per word (total verse area divided by number of words), and representative letter height. The three measures were found to parallel each other closely within each verse and between the three verses in each sample.

Average word length varies slightly more than the other measurements, is easy to measure and calculate, and has been studied more often than the other measures, so we chose this as the final criterion of micrographia.

In 3 cases, the baseline handwriting was so large, unruly, and bizarre ("psychotic handwriting") that it was not measurable. For this reason, as well as the possibility that reduction in size of these handwriting samples would more likely be due to the antipsychotic effect of the drug than to an extrapyramidal micrographic effect, these patients were excluded from the study.

Akinesia ratings were made independently by one of the authors on an extrapyramidal symptom rating scale (8). The akinesia scale was modified as follows: 0=none; 1=mild (subjectively the patient feels "slowed up" *and* objectively there is a subtle motoric slowing, patients walk less briskly, arm swing is somewhat reduced, face conveys less expression, spontaneous gestures and movements are reduced); 2=moderate; and 3=severe (loss of facial expression, arm swing markedly reduced, and patient moves and walks very slowly).

Results

During the course of treatment with antipsychotic medication, 10 of the 21 patients developed akinesia (9 mild, 1 moderate).

Before drug therapy there was no significant difference in handwriting size between those patients who eventually developed akinesia (mean word length=2.13 mm, SD=.36), those who did not develop akinesia (mean=2.27 mm, SD=.52), and the control group (mean=2.16 mm, SD=.30). When the akinetic patients developed this symptom, their handwriting constricted to a statistically significant degree (mean=1.93 mm, SD=.31, $t=2.457$, $p<.05$). However, the nonakinetic patients' handwriting constricted just as much at some time during their course of treatment ($2.05\pm.56$, $t=4.115$, $p<.01$), as did that of the control group ($1.95\pm.25$, $t=6.8754$, $p<.001$).

They are also with the Department of Psychiatry, University of California at Los Angeles, where Dr. Shackman is Assistant Clinical Professor of Psychiatry, Dr. Van Putten is Associate Professor of Psychiatry, and Dr. May is Professor of Psychiatry.

This study was supported in part by the Research Service, Veterans Administration.

The authors thank Lorraine Wittman and La Vonna Newton for assistance in collecting and preparing the data.

The handwriting of 7 of the 10 patients who became akinetic showed constriction. In 1 case handwriting size remained unchanged, and in 2 cases the handwriting actually expanded. However, 10 of the 11 nonakinetic patients' handwriting constricted at some time during the course of drug treatment. Further, a group of control subjects demonstrated the same degree of handwriting constriction at some point during an equivalent period of study.

Discussion

Our study demonstrated that the handwriting of a group of medicated schizophrenics tended to constrict when these patients became mildly akinetic. However, when examined in a rigorous prospective design, handwriting constricted just as much at some time in a group of nonakinetic medicated schizophrenics and in a group of normal controls. This observation is in accord with those of Rifkin and associates (3), who found that change in size of the area of a copied paragraph did not distinguish between those patients with mild akinesia and those without. We conclude that micrographia is not a reliable correlate of mild akinesia.

Use of Propranolol in the Treatment of Postencephalitic Psychosis

BY HERBERT A. SCHREIER, M.D.

Propranolol, a β-adrenergic blocking agent, has been used extensively in medicine, particularly in cardiology. Recently, reports have appeared of this drug's efficacy in such diverse conditions as anxiety (1, 2), migraine (3, 4), and chronic drug-refractory schizophrenia (5). Elliott (6) reported on its effectiveness in controlling irritability and/or "episodic belligerence" that occur after brain injury from trauma or anoxia. The following is a case report of the successful treatment with propranolol of a 12-year-old boy who developed a psychosis during an acute encephalopathy of unknown etiology.

Case Report

John is a 12-year-old boy who was admitted to Children's Hospital Medical Center (CHMC) in a fluctuating state of consciousness. Eleven days before his admission he had started having severe headaches that were not relieved by aspirin. Three days before his admission he had a grand mal seizure and was admitted to a local hospital, where he was described as alert and afebrile postictally. Results of general physical and neurologic examinations were normal. A lumbar puncture at that time showed protein of 36 mg/100 ml, glucose of 56 mg/100 ml, a white count of 180 (mostly lymphocytes), and a normal blood count and urinalysis. He also had a normal skull series and cinetomography brain scan. He was treated with diphenylhydantoin, 200 mg/day, and phenobarbital, 120 mg/day, and was transferred to CHMC on the 4th hospital day when he became disoriented to time and place.

On admission, John was afebrile and had normal vital signs. He was alert, watched people, and was able to follow simple commands after only a few seconds' delay, but he would not speak or answer questions. A neurologic exam revealed asymmetric deep-tendon reflexes at the knees, the right being brisker than the left, a few beats of clonus at both ankles, and bilateral Babinski reflexes. He continued to be disoriented and had occasional episodes of lethargy, alternating with episodes of extreme agitation. During the latter episodes he used obscene language with marked sexual overtones, which was described as atypical behavior for him. On his 2nd day at CHMC he had a second grand mal seizure. A repeat lumbar puncture revealed 370 white cells, 100% lymphocytes, 60 red blood cells, a total protein of 18 mg/100 ml, and a glucose of 79 mg/100 ml. CSF analysis, including fungal, tuberculosis, viral, bacterial, and cytological studies, was negative. John continued to have episodes of lethargy alternating with delirious agitation, and on the 3rd hospital day he exhibited clinical signs of increased intracranial pressure, requiring the use of mannitol. He was also started on dexamethasone sodium phosphate, 4 mg I.V. every 6 hours.

Received Feb. 15, 1979; accepted March 12, 1979.

0002-953X/79/07/0840/02/$00.35 © 1979 American Psychiatric Association

An EEG performed on the 2nd day of hospitalization showed an excess of slow activity, with somewhat higher amplitudes on the left side. His agitation was not controlled by chloralhydrate and/or chlorpromazine.

On the 17th hospital day John suddenly seemed alert, with an appropriate mental status, but 3 days later he again exhibited periods of disorientation, agitation, and lethargy. Steroids were discontinued, with no benefit. On the 20th day the patient became alert and oriented but started hearing voices and reported seeing bugs in his bed. At times he was verbally abusive (in marked contrast to his premorbid functioning), and he attempted to flee the hospital several times. Propranolol, 20 mg b.i.d., was begun and increased over the next 2 days to 100 mg/day. At that dose John had no further episodes of agitated behavior, was alert and oriented, without hallucinations. He was described by his grandfather as being regressed in his behavior, acting more like a sibling who was 8 years old. He was discharged on the 25th day on diphenylhydantoin, 300 mg/day, propranolol, 100 mg/day, and chlorpromazine, 100 mg at bedtime as needed.

At home, John continued to exhibit regressed behavior (e.g., asking for toys of the type he had not played with in years) and exhibited clinging behavior toward his grandfather and some increased sibling rivalry. Over the next 2 weeks there were no aggressive incidents or indications of psychosis. The dosage of propranolol was decreased over several days. Chlorpromazine had not been given for over a week. The day after his last dose of propranolol, John became irrational and belligerent while shopping with his grandfather and had to be taken home. At home, he became increasingly aggressive, wrecking his room, scattering and tearing clothes, and breaking pictures. Propranolol, 100 mg/day, was resumed and no further incidents of this nature occurred. One month later, John was showing less regressive behavior and no evidence of the former belligerence or psychosis so propranolol was again tapered, without further incident. A year later he continues to do well and has regained his former level of functioning at school and in his social relations. The diagnosis was encephalitis, probably of viral origin, with an organic psychosis.

Discussion

Propranolol has been shown to be useful in treating atypically belligerent behavior in some patients after concussions and anoxia. This case probably represents the successful treatment of a psychosis with belligerent behavior that developed in a 12-year-old boy after an encephalopathy of infectious origin. In Elliott's report (6) the patients with belligerent behavior did not respond to diphenylhydantoin or a variety of sedatives, benzodiazepines, or, in one case, phenothiazines. In some of his cases, the belligerence recurred when propranolol therapy was discontinued after several weeks. In that group of patients, symptoms were relieved after administration of propranolol was resumed.

Propranolol's mechanism of action on the central nervous system is poorly understood. It appears to have effects on mood and behavior that are not related to its β-adrenergic blocking potential. Caution should be observed in patients with cardiac problems, asthma, pulmonary disease, or diabetes (7).

A Double-Blind Evaluation of Nomifensine and Imipramine in Depressed Outpatients

BY AUSTIN MCCAWLEY, M.D.

Nomifensine maleate has been effective as an antidepressant in a number of clinical studies conducted in this country and in Europe (1, 2). The drug has properties similar to the tricyclic antidepressants but is not identical to them; its chemical structure appears to be intermediate between imipramine and methylphenidate. It has an early onset of action, little anticholinergic activity, and, in the animal studies, no addictive potential. Nomifensine maleate is 8-amino-1,2,3,4-tetrahydro-2-methyl-4-phenylisoquinoline maleate. This study compared nomifensine maleate with imipramine HCl in 20 depressed outpatients.

Received Dec. 13, 1978; accepted Feb. 5, 1979.

Dr. McCawley is Director of Psychiatry, Saint Francis Hospital and Medical Center, 114 Woodland St., Hartford, Conn. 06105, and Associate Professor of Psychiatry, University of Connecticut, Farmington, Conn.

Method

Patients were selected for the study on the basis of the following criteria: 1) evidence of primary affective disorder (depression) in accord with a predetermined checklist, 2) age between 18 and 65, 3) a minimum baseline total score of 20 on the Hamilton Depression Scale with at least a score of 2 for depressed mood, 4)

0002-953X/79/07/0841/03$00.40 © 1979 American Psychiatric Association

a total rating of 14 on the Beck Depression Inventory, 5) onset of symptoms at least 4 weeks before entry into the study, and 6) illness duration less than 6 months. Patients were excluded for a number of reasons, including medical illness, pregnancy, the need to take other medication, and chronic abuse of alcohol or drugs.

Two groups of patients, 13 of whom received nomifensine and 7 imipramine, were studied in a double-blind parallel group fashion established by random assignment. Patients who were already taking psychotropic medication were given a placebo washout for 7 days before starting the study medication. The dosage regimen for both drugs was 50 mg b.i.d. for 1 week, 50 mg t.i.d. for 1 week, and then 200 mg/day if the symptoms had not remitted. The duration of the study was 28 days, but some patients were continued for periods up to 6 months. Statistical calculations for this report are made on the response after 28 days. In the interest of brevity, the extensive evaluations done at baseline will not be detailed. The instruments used for evaluation in this report are the Hamilton Depression Scale, done at weekly intervals, and the Clinical Global Impression Scale, done at baseline, day 14, and day 28. At each weekly evaluation, the patient completed the Hopkins Symptom Check List.

All patients received a physical examination and extensive laboratory tests, including SMA/12, CBC, urinalysis, and ECG at baseline and day 28. Vital signs were recorded weekly.

Results

Nineteen patients completed the study. The mean Hamilton Scale scores of the two groups before treatment were almost identical (25.92 and 26 for nomifensine and imipramine, respectively), as were the mean difference scores of the group (14.85 and 14.5).

When the samples were combined to determine whether the group as a whole had improved significantly, the mean difference score was found to be 14.74 (SE=1.41); this was significant ($t=10.469$, $p<.001$).

Patients were rated by the physician as very much improved, much improved, minimally improved, or unchanged. Chi-square analysis of these ratings agreed with the Hamilton Depression Scale scores in indicating that imipramine and nomifensine were equally effective.

At the onset of the study no attempt was made to distinguish between endogenous and reactive depressions. In some cases, this would have been difficult. However, there was a group of 11 patients (3 on imipramine and 8 on nomifensine) with unusually difficult situational or interpersonal problems in whom the depression appeared to be reactive. These two small groups were compared, with interesting results. It appeared that the initial mean scores of the groups did not differ from each other or from the mean score of the larger group. Following treatment, however, the scores of the two groups differed significantly in favor of the nomifensine group ($t=3.88$, $df=9$, $p<.05$). A Wilcoxon test did not reach this significance level but did tend to confirm that nomifensine was superior to imipramine in the treatment of these reactive depressions. The small size of the groups and the fact that this analysis was retrospective do not allow one to draw conclusions, but this observation would appear to merit further study.

Side Effects

One patient was withdrawn from the study after she developed a syndrome of inappropriate antidiuretic hormone secretion. She had been a very unreliable subject, had taken only 50 mg/day of nomifensine, and was about to be withdrawn from the study for this reason. However, there were a number of capsules unaccounted for in the medication she returned, which raised the (unresolved) question of whether she took an overdose. This syndrome has been reported in psychiatric patients as a side effect of several drugs and also in unmedicated patients (3). Therefore, there is some question whether this was in fact a side effect of nomifensine; it has not been reported in any of the considerable number of other studies now completed.

All other side effects were mild, transient, and easily managed. Nausea, headaches, rapid pulse, and flushing were each reported by two patients. Paresthesia in the legs, palpitations, faintness, a metallic taste, and a slight high were each reported by one patient. Four patients on nomifensine had no side effects whatever, whereas all of the patients on imipramine had at least one side effect. Insomnia was not reported by the patients on nomifensine. A number of slightly elevated laboratory tests were observed, but they had no clinical significance and followed no significant pattern.

Conclusions

The results of this study indicate that nomifensine is as effective as imipramine in treating depression. There were some indications that it may be more effective in reactive depressions.

Many of these patients were followed beyond the 28-day study period. They sustained their improvement, and one of the patients on nomifensine who was reported to be unimproved on day 28 showed a dramatic improvement after 6 weeks. For several reasons this patient had reached the maximum dose of 200 mg later in the course of treatment. In nearly all of the patients who were followed, the treatment evolved from pharmacotherapy to a more psychotherapeutic form of treatment. There were numerous psychological issues that had to be dealt with in psychotherapy, and in this study, as in others, it became clear that depression is not simply a biochemical process.

Lithium Treatment in Older Patients

BY STEVEN P. ROOSE, M.D., STANLEY BONE, M.D., CATHERINE HAIDORFER, R.N., DAVID L. DUNNER, M.D., AND RONALD R. FIEVE, M.D.

The purpose of this paper is to describe our experience with maintenance lithium therapy in patients over the age of 60. As the indications for the use of maintenance lithium therapy broaden, clinicians will encounter a greater number of older patients who are taking lithium or beginning lithium treatment. There is a paucity of clinical data specifically focused on medical problems related to lithium treatment in patients over 60 (1, 2). We will report assessments of the medical status of 31 patients over the age of 60 who are in active treatment in the Lithium Clinic of the New York State Psychiatric Institute.

Method

All patients over the age of 60 in the Lithium Clinic filled out a questionnaire that surveyed side effects, medical history (before and after lithium treatment), and current indications of acute or chronic medical problems. In addition, each patient was interviewed individually to supplement or clarify responses to the questionnaire. All patients met the diagnostic criteria of Feighner and associates (3) for primary affective disorder and gave written informed consent to participate in the study. In addition to the questionnaire, all patients had had a complete physical examination, complete blood count, blood chemistries, and electrolyte studies within the past year. A 12-level ECG was performed on all patients in the study and read by an attending cardiologist.

Results

Patients ranged in age from 60 to 79 years, with a mean age of 67 years. They had been treated with lithium for 1 to 10 years.

The most unexpected result of this survey was that 9 out of 31 patients had no regular medical contact other than the Lithium Clinic. Thus, our subspecialty clinic was in fact serving a primary care function for about 30% of these patients.

The most frequent chronic medical problem was hypertension, which was reported in 20% of the patients. In all cases the hypertension was satisfactorily controlled with α-methyldopa, with no increase in depressive episodes. Arthritis and hypothyroidism were each reported by 10% of the patients, and in 1 case the hypothyroidism had developed shortly after lithium treatment was initiated.

There were 4 episodes of lithium toxicity in these 31 patients during an 18-month period. In the same time period there were only 2 cases of toxicity in 164 lithium-treated patients under 60. This difference is statistically significant ($\chi^2=8.32$, $p<.01$, Yates's correction applied). As reported elsewhere (4) two patients developed cardiac sinus node dysfunction that could be directly attributed to lithium therapy as demonstrated by Holter monitoring of cardiac rhythm both when the patients were taking lithium and when they were lithium-free.

Only 13 of the 31 patients had completely normal ECG tracings. Five patients had arrythmias—3 cases of sinus tachycardia (rate>100), 1 case of sinus bradycardia (rate<55), and 1 case with frequent atrial premature contractions. Fourteen patients had evidence of conduction defects—10 cases of incomplete atrial-ventricular block (PR interval>.20 seconds), 2 cases of right bundle branch block, and 2 cases of incomplete ventricular conduction defect.

Discussion

The patient over the age of 60 is prone to develop lithium toxicity, and it appears that these episodes can fulminate more rapidly and at lower serum lithium levels than those seen in younger lithium-treated patients. Consequently, we have tended to keep this elderly patient population at a somewhat lower maintenance lithium level (.6–.7 mEq/liter), and to date we have not noted an increased number of affective episodes, which would indicate decreased prophylactic efficiency. Whether this lithium toxicity diathesis is a reflection of an increased sensitivity to lithium or of decreased renal clearance is not yet determined. In general, it appears that older patients can be safely

maintained on lithium despite various medical problems and a proneness to develop toxicity. Such patients' lithium levels should be closely monitored, and they should be followed by a primary care physician, with routine physical examinations, ECGs, blood chemistries, and evaluations of kidney and thyroid function. The fact that 30% of our patients had no primary care physician is distressing.

The ECG results initially indicate no consistent pattern of abnormalities. However, the limitations of a routine ECG and the small number of subjects make it inadvisable to draw conclusions about the cardiac effects of lithium from these data. Sinus node dysfunction is one proven side effect of lithium treatment, but whether there are others remains to be seen. It is clear that larger, prospective studies of the effects of lithium on cardiac function are necessary.

Behavioral Treatment for Raynaud's Disease: A Comparative Study with Long-Term Follow-Up

BY ALAN M. JACOBSON, M.D., THEO C. MANSCHRECK, M.D., AND ELIZABETH SILVERBERG, PH.D.

Biofeedback and relaxation techniques are being evaluated as possible treatments for many psychosomatic conditions, including Raynaud's disease, which causes considerable pain and discomfort in the fingers and toes after exposure to even mildly cool temperatures. Behavioral treatment for Raynaud's disease has focused on teaching patients to warm digits to abort or prevent painful episodes. Previous case reports (1, 2) and uncontrolled outcome studies (3) have suggested that an approach which combines biofeedback and relaxation in an individually tailored program can be clinically beneficial in the treatment of this disorder.

Recent studies of hypertension (4) and migraine headaches (5) have suggested that relaxation alone may be as effective as a combined biofeedback/relaxation approach. Because there have been no comparisons of these two approaches in Raynaud's disease, we decided to examine the benefit of relaxation and finger temperature biofeedback in patients with clinically significant Raynaud's disease.

Method

We formulated 3 specific hypotheses:

1. Finger warming would be greater in patients using biofeedback and relaxation than those using relaxation only.
2. There would be more clinical improvement in the combined-treatment patients than the relaxation-only patients.
3. Clinical improvement would be associated with finger warming demonstrated in laboratory sessions.

The subjects (N=12) were selected on the basis of the following criteria: 1) a diagnosis of currently symptomatic Raynaud's disease, 2) absence of concurrent collagen vascular disease, 3) at least a two-year history of symptoms, 4) no prior sympathectomy or gangrenous changes in the digits. Informed consent was obtained from all patients after the procedures had been fully explained.

After an initial history-taking session, patients were randomly assigned to one of two treatment conditions, biofeedback and relaxation or relaxation only. These groups were not significantly different in age or duration of illness. All patients were first taught a simple relaxation technique (6) that required systematic muscle relaxation and focused attention in a single half-hour session. They were asked to practice this technique twice daily during the treatment period. The biofeedback group was also taught to use a temperature trainer with auditory and visual feedback.

The sessions, which consisted of two 5-minute trials, were given twice weekly for 6 weeks. During the trials the relaxation group practiced relaxation and the biofeedback group used the temperature trainer to warm the right forefinger.

Laboratory outcome was measured by the change in finger temperature during each trial. Forehead temperatures were recorded at the same time to control for general body warming. Clinical results were based on patients' ratings of symptom severity 1 month and 2

[b]No follow-up.

years after treatment. Because all patients expected to receive biofeedback training, those in the relaxation-only group were offered biofeedback one month after the study period. Four of the 6 patients in this group eventually underwent biofeedback treatment.

Results

Both treatment groups demonstrated consistent finger temperature increases during biofeedback or relaxation trials (see table 1). Temperature increases were noted in 53 of 72 trials for the biofeedback group and in 62 of 72 trials for the relaxation group. However, the hypothesis that finger warming would be greater in the biofeedback group than the relaxation group was not supported. The relaxation group averaged a 1.4°C increase per trial while the biofeedback group demonstrated a 0.5°C increase per trial ($t=1.97$, $df=10$, $.05<p<.10$).

Our second hypothesis, that clinical improvement would be greater in the biofeedback group, was not supported. Five patients from each group reported a decrease in symptom severity at 1-month follow-up. Typically, patients tolerated cold better than before treatment and remarked that emotional stress was less likely to trigger symptoms. To our surprise, clinical benefit was not positively correlated with ability to warm fingers in the laboratory setting. For example, patient 1 was among the best responders clinically but showed below average finger-warming ability in the experimental sessions compared with others in the biofeedback group.

Long-term comparisons between the two groups were not possible because 4 of the 6 relaxation patients eventually received biofeedback training. At 2-year follow-up, 7 of the 11 patients contacted noted continued clinical benefit, characterized by less severe and less frequent episodes. This improvement was maintained regardless of the initial treatment regimen. Six of the 7 long-term responders noted that continued benefit was dependent on regular practice of relaxation exercises. For example, patient 7 found that symptom severity increased after only 2 days without practice. Interestingly, two other patients (patients 3 and 6), who reported little improvement at 2-year follow-up, said they had stopped regular relaxation practice because of "laziness" but found that relaxation on even an occasional basis lessened the severity of symptoms.

Comment

The most interesting finding of this study is that combined relaxation and biofeedback treatment appears to have not only short-term but long-term clinical benefit for patients with Raynaud's disease. This continued benefit seems to be dependent on regular practice of relaxation. Previous reports of behavioral approaches for treating Raynaud's disease provided only limited evidence for long-term benefit (1–3). In fact, few studies of biofeedback and relaxation treatments for other conditions have reported on the long-term benefit of these approaches.

Also of interest is the finding that treatment with relaxation alone matches the short-term benefit of biofeedback treatment. This is consistent with the finding of recent reports on the treatment of migraine headaches (5) and hypertension (4) but requires corroboration because the relative superiority of biofeedback may not be demonstrable on measures of laboratory change or short-term response. Rather, the value of biofeedback may be in the specific learning of a new response to stressful life events, which can only be assessed with long-term follow-up.

This study could be faulted for the lack of a no-treatment control group; placebo factors rather than the specific effects of biofeedback or relaxation might ac-

count for the reported benefit. However, there are two findings which suggest that the effects go beyond placebo factors. First, patients noted a regular relationship between relaxation practice and clinical benefit and when the practice stopped, clinical benefit ceased. Second, these practice-related benefits persisted long after the original treatment period. Certainly, further studies with both a control population and blind observers will be an important next step in these investigations. It does appear that a behavioral approach will provide an additional method for treating Raynaud's disease. This gives the psychiatrist new opportunities for treating patients who have conditions beyond the scope of traditional psychotherapeutic techniques.

Appearance of Manic Psychosis Following Rapid Normalization of Thyroid Status

BY ALLAN M. JOSEPHSON, M.D., AND THOMAS B. MACKENZIE, M.D.

The appearance or exacerbation of psychiatric symptomatology early in the treatment of hypothyroidism is well documented (1). The possibility that the appearance and severity of these symptoms may depend on the speed with which thyroid status is normalized has been mentioned (2). However, a clinical course compatible with a manic psychosis has not been well described. We will describe a case in which mania was observed in a hypothyroid woman treated with thyroxine.

Case Report

Ms. A, a 34-year-old woman, was admitted to the medical service of the University Hospitals on April 10 after her family brought her to the emergency room because of progressive insomnia and agitation of 5 days' duration.[1] A psychiatric consultation was sought on the day of admission.

Four years earlier the patient had been admitted to a general hospital because of "agitation, insomnia, mild euphoria, and distractibility." She was discharged after 6 days with a diagnosis of "emotional lability and probable manic-depressive state." Thyroid indices and psychiatric consultation were not obtained. Three years before her admission, a diagnosis of Grave's disease was made after thyromegaly was noted; anxiety was her only symptom. The patient was given 44 mCi of ^{131}I four months before her admission.

On March 30, her tendon reflexes were noted to be moderately prolonged and thyroid studies revealed a hypothyroid state (T_4=1.6 μg/dl, T_3 uptake=0.79, thyroid index=1.3 μg/dl, TSH=133 μIu/ml). No psychiatric abnormality was described at that time. On April 1, her family noticed an increased interest in religious themes. As directed by her physicians, she took 150 μg of thyroxine daily on April 3, 4, 5, and 6. On April 5, she was described as alternately tearful and euphoric. She was ordinarily a "good listener," but friends now found her to be garrulous and unable to focus her thoughts. She discontinued the thyroxine on April 7 because she was "getting hyper." Over the next 3 days increasing preoccupation with religious concerns and progressive agitation and insomnia were noted.

Ms. A was taking no medications on admission and denied a history of drug use or excessive alcohol intake. There was no family history of endocrine or psychiatric disorder.

On admission positive physical findings included brisk reflexes, diaphoresis, and a pulse of 110. Ms. A was exophthalmic and complained of sleeplessness. Her motor activity was mildly retarded, with no unusual posturing or grimacing. Her affect fluctuated between tearfulness and elation and she demonstrated thought blocking and delusional thinking of a religious nature. She was oriented to time, place, and person.

Ms. A was started on 2 mg of haloperidol p.o. h.s. Thyroid indices at admission were normal (T_4=6.5 μg/dl, T_3 uptake=0.86, thyroid index=5.6 μg/dl) with TSH remaining elevated at 30 μIu/ml. Laboratory studies on admission, including plasma cortisol and urinary hydroxycorticosteroids, were within normal limits. An EEG obtained on April 17 revealed excessive and diffuse bitemporal slowing. A sleep-deprived EEG obtained on April 24 with NP leads showed no seizure activity.

She continued to show marked affective lability and on her third hospital day was transferred to the psychiatry service. She also continued to have insomnia and grandiose delusions, such as believing that "everyone on this ward is a doctor because I am a special patient." Concomitant cognitive examination showed no impairment. She was placed on loxapine succinate, 75 mg/day p.o., and simultaneously 150 μg of thyroxine was resumed at the recommendation of the

endocrinology consultant. Within 3 days marked improvement of her insomnia and delusional thinking was noted. In view of the hypomanic quality of Ms. A's behavior, lithium carbonate, 1800 mg/day, was started 4 days before her discharge.

Ms. A was discharged 2 weeks after admission on a regimen of loxapine, 25 mg p.o. h.s., lithium carbonate, 1800 mg/day p.o., and thyroxine, 150 μg 4 days a week and 75 μg 3 days a week. Her lithium and loxapine were subsequently discontinued, and there was no return of psychotic symptomatology.

Discussion

This patient's insomnia, mood lability, grandiosity, garrulousness, and psychomotor agitation satisfied Research Diagnostic Criteria for mania (3). The appearance of these symptoms followed rapid normalization of her thyroid status (600 μg of thyroxine in a 4-day period). The progressive appearance of her manic symptomatology over a 7-day period is consistent with observations that peak physiologic activity of thyroxine occurs 7–10 days after administration (4). Her symptoms were readily controlled by neuroleptics and her clinical symptoms abated within 2 weeks. Withdrawal of psychotropic medication was accomplished uneventfully.

Although her mania occurred in the context of a rapid normalization of her thyroid status, the underlying neurobiologic mechanisms are unclear. Thyroid hormone is known to play a role in modulating catechol receptor sensitivity (5). Animal research has shown a decreased receptor sensitivity to CNS catecholamines in hypothyroidism, accompanied by a compensatory increase in catechol concentration (6, 7). If such an adjustment occurs in human subjects, then rapid administration of thyroxine, abruptly augmenting catechol receptor sensitivity, could precipitate a hypercatecholaminergic state. The catecholamine theory of affective disorder proposes that in susceptible individuals, such an excess of catechol activity is the neurochemical basis for mania (8). This patient's susceptibility to affective disturbance was suggested by her history of hospitalization for "probable manic-depression." We speculate that the rapid administration of thyroxine precipitated a manic episode in a person disposed to affective instability.

Should this patient's clinical course be regarded as an instance of secondary mania? In their recent review of this syndrome, Krauthammer and Klerman (9) did not mention thyroxine administration as an etiology. According to their criteria, this patient's history of affective disorder would militate against the diagnosis of secondary mania. However, her previous affective disturbance appeared within a year of the discovery of hyperthyroidism and may have been an organic affective syndrome. In support of the diagnosis of secondary mania are the late age of onset, close temporal proximity to administration of thyroxine, negative family history of psychiatric disorder, rapid resolution of the psychosis, and the diffusely abnormal EEG at the height of the symptoms. We suggest that alteration in thyroid status merits consideration as a possible antecedent to secondary mania.

The "Wish Book" in Child Psychotherapy

BY JOEL A. MOSKOWITZ, M.D.

Mail order catalogs can serve as a unique window into the inner fantasy world of children in therapy. Slavson (1) stated that play therapy for young children was developed because of the inadequacy of language as a medium of expression. When the child is supplied with appropriate materials, he conveys symbolically his fantasies and preoccupations. Slavson refers to the use of toy guns, soldiers, darts, clay, dolls, and water. A more structured but highly evocative medium is the use of the mail order catalog to involve, stimulate, and benefit troubled children, including adolescents. Even in pioneer days it was well known that the Sears catalog, for example, opened for isolated settlers wide vistas of needed and wished for clothing, utensils, and building materials. A collection of catalogs in the therapist's office provides a new way to penetrate the initial silent barriers that often prevail and to elicit useful therapeutic data. In a sense, the world is a projective test. Opinions, attitudes, and feelings may be elicited by asking the patient to comment about anything he or she observes. Inquiring about the child's ideas relevant to something he or she finds interesting in a catalog is less threatening than posing more direct questions.

The catalog the child picks tells the therapist what the child likes. The therapist must actively focus the child's attention on the mail order catalog and will find it easy to engage the child in conversation about such items as model airplanes or the latest stereo equipment. There should be a wide selection of readily accessible catalogs. Catalogs from the major mail order department stores are obvious choices, but many specialty catalogs dealing with sports equipment, new homes, games, scientific instruments, radio equipment, books, magic, travel, schools, records, etc., are also available on written request.

The use of the mail order catalog is not a separate form of therapy. It is a clinical tool designed to serve as a medium of conversation between therapist and child and to help the therapist assess the child's mood, attitude, temperament, and even perceptive and cognitive abilities. Depending on his or her age, the child may merely look at the pictures or may study actively the relative costs of items he or she has long desired. How children envision the way they would obtain the sought-after prize, and what they think it would do for them, are significant questions. In a way, the mail order catalog makes concrete the classical question, "Supposing you had five wishes, what would you wish?" In fact, Sears, Roebuck Co. calls their Christmas catalog "The Wish Book."

With more retiring children, the therapist may have to be quite active and thumb through the pages of a catalog commenting about the contents from his own point of view. This requires divulging information about oneself, and therefore is not in accord with customary psychoanalytic approaches. However, many children respond when their attention is focused on a relatively neutral book or magazine. The therapist, armed with the knowledge of the child's presenting problem, can skillfully select particular catalogs or certain sections about which he might comment in order to trigger some response from the child. A few case vignettes will help illustrate this approach.

Case Vignettes

Vignette 1. Ian, a 7-year-old boy, had become extremely unmanageable in class; he was hostile, uncooperative, inattentive, and negativistic and was being considered for expulsion. An obvious precipitant about which he refused to speak was the birth of a brother. In the opening session of therapy I allowed him to rummage in the catalog box. He selected a Montgomery Ward catalog and leafed through it carelessly. Upon reaching the section dealing with cribs and baby supplies, he became irritable and tore the page, although he had previously commented that there was nothing troubling him and he was pleased that he had a new baby brother. This behavior gave us an opportunity to discuss the situation in further detail, which led to a reduction in his tension and anger toward the new rival in the family.

Vignette 2. Lynn, an 11-year-old girl, after initially expressing disdain for psychiatry, her parents, and people in general, seemed pleased to examine a catalog from I. Magnin. The luxurious clothes were something she admired but had been told she could never hope to obtain. Her mother called her ugly, fat, and stupid. In talking about the color, styles, and the kinds of people who would purchase such expensive garments, Lynn displayed a remarkable sophistication and sensitivity in the areas of self-image, sexuality, economics, and oedipal competition. She spoke of her mother's fear of Lynn's growing sexuality and noted that her father seemed to like her better than her mother in many ways.

Vignette 3. Sharon had been in a class for the educationally handicapped. At age 9 she was 2 years below grade level and had almost no reading skills. Her referral for psychiatric evaluation was prompted by an episode of petty theft. She came from an affluent middle-class family. The catalog experience revealed that although she was dyslexic, she could readily identify graphic symbols and understand their function. Her sense of deprivation seemed rooted in an emotional distance from her parents, who considered her retarded. Her mother had a degree in geology but rarely shared this interest with her daughter. Sharon selected a rock hunter's catalog. She spoke about the methods of distinguishing rocks by

Received Feb. 5, 1979; accepted March 1, 1979.

hardness, color, and other physical properties. This opened a level of communication between mother and daughter that was immensely therapeutic.

Vignette 4. Jerry, a precocious 6½-year-old boy, was described as hyperkinetic by school authorities. He made a whirlwind entry into my office. He was extremely distractible and often apologized for his clumsiness. To the surprise of his mother, who accompanied Jerry to the office, his restlessness diminished abruptly when he focused his attention on a catalog of scientific instruments. He told me of his interest in science fiction and building things. He then turned to a real estate catalog and shared his ambition of becoming an architect. A seldom perused catalog of orthopedic appliances seemed to be of particular interest to Jerry. He explained that another little boy he knew had been hit by a car and was wearing a brace. He had stopped playing with the boy because he was afraid to look at the brace. He was able to use the orthopedic catalog to desensitize himself to such threatening objects and to explore his feeling about injury and loss of bodily function. He and his parents then were able to cooperate with a trial of methylphenidate, which was successful.

Discussion

Like my experience with using magic (2) in the psychotherapy of children, the mail order catalog provides an interesting alternative to conventional therapeutic devices in child psychotherapy. In addition to being a vehicle for communication, it is a potential source of projective and cognitive assessment.

Decreased Serum Prolactin in Opiate Withdrawal and Dopaminergic Hyperactivity

BY MARK S. GOLD, M.D., DONALD R. SWEENEY, M.D., PH.D., A.L.C. POTTASH, M.D., AND HERBERT D. KLEBER, M.D.

We have recently proposed a noradrenergic hyperactivity hypothesis to explain the signs and symptoms of opiate withdrawal (1). However, a dopaminergic hyperactivity hypothesis has also been proposed; it is supported by a large number of animal studies (2, 3). Serum prolactin is predominantly controlled in vivo and in vitro by an inhibitory dopaminergic mechanism (4). Consistent with this control mechanism, augmentation of dopaminergic function results in decreases in serum prolactin, and inhibition of dopamine function results in increases (4, 5).

To begin evaluating these hypotheses we measured serum prolactin in five opiate addicts during significant opiate withdrawal and after suppression of symptoms by clonidine. In addition, to provide a drug-free baseline we measured serum prolactin in these addicts 2 weeks after they had been discharged from the hospital and were free of clonidine and opiate.

Received Jan. 8, 1979; accepted Feb. 5, 1979.

Dr. Gold is Vice-President for Basic Research and Dr. Pottash is Vice-President for Applied Research, Psychiatric Institutes of America. Dr. Gold is also Director of Research and Training, Fair Oaks Hospital, 19 Prospect St., Summit, N.J. 07901, where Dr. Sweeney is Clinical Director and Dr. Pottash is Associate Medical Director. Drs. Gold and Sweeney are Lecturers, Yale University School of Medicine, where Dr. Kleber is Clinical Professor of Psychiatry. Dr. Kleber is also Director, Substance Abuse Unit, Connecticut Mental Health Center.

Method

The subjects were five opiate addicts who had been maintained on 15–60 mg of methadone for 2–10 years. All gave informed consent to participate in a study that involved abrupt discontinuation of methadone and administration of 5 μg/kg of clonidine after at least 36 hours with no opiate administration. A research nurse clinician observed the presence or absence of 21 withdrawal signs and symptoms every 30 minutes, as described previously (1), with the subjects at bed rest after an indwelling venous catheter was in place. Ratings were done simultaneously with blood samples taken 60 minutes before clonidine administration, at the time of administration, and 60 and 120 minutes after clonidine administration. While the subjects were taking methadone, prolactin levels were not measured due to the stimulatory effects of methadone on serum prolactin. Opiate-free samples were taken by venipuncture 2 weeks after hospital discharge. All samples were placed on ice and centrifuged within 1 hour. Serum was frozen at −20°C until radioimmunoassays were performed in duplicate (6).

Results

As reported previously (1), clonidine caused a rapid and significant decrease in the signs and symptoms of opiate withdrawal. Opiate withdrawal symptoms decreased from a mean (±SE) just before clonidine ad-

0002-953X/79/07/0849/02/$00.35 © 1979 American Psychiatric Association

ministration of 15.2±0.7 to 3.6±0.8 at 60 minutes after clonidine administration (paired t=10.3) and to 0.6±0.4 120 minutes after clonidine administration (paired t=16.7, p<.001). Serum prolactin was significantly decreased from a mean (±SE) just before clonidine administration of 10.8 ng/ml±1.0 to 8.2±0.8 at 60 minutes and to 7.0±0.8 at 120 minutes after clonidine administration (t=3.92, p<.02). Serum prolactin was significantly reduced during the peak of opiate withdrawal to a mean of 10.2±0.7 ng/ml compared to a mean of 13.6±0.9 ng/ml for the assay done when patients had been free of opiate and clonidine for 14 days (t=3.50, p<.02).

Discussion

Significant decreases in serum prolactin are normally attributable to the administration of medications that stimulate dopamine receptors or augment dopamine release or neurotransmission (4, 5). The decreased serum prolactin reported here for patients in opiate withdrawal supports a hypothesis of dopamine hyperactivity in opiate withdrawal (2, 3). However, as the symptoms of opiate withdrawal were reversed and virtually eliminated by clonidine, the serum prolactin did not return to preclonidine or postaddiction levels. This suggests that dopaminergic hyperactivity accompanies opiate withdrawal but is not directly related to the symptoms or signs of withdrawal. Clonidine administration has not been reported to produce any changes in serum prolactin in humans (7). Although clonidine neither augments dopamine neurotransmission nor stimulates dopamine receptors, it is possible that the further decreases in serum prolactin represent continued dopaminergic hyperactivity, which is present in patients with symptomatic or asymptomatic opiate withdrawal. Clonidine may produce the additional decrease in serum prolaction through nondopaminergic mechanisms (6).

We have suggested that endogenous and exogenous opiates increase serum prolactin by inhibition of dopamine neurotransmission (8). Withdrawal from chronic opiate administration might be expected to release dopamine neurons from inhibition and reduce serum prolactin. Animal studies (2, 3) have found dopaminergic hyperactivity in opiate withdrawal and there has been speculation on the relationship of this hyperactivity to the pathophysiology of withdrawal. However, the failure of clonidine to reverse both the opiate withdrawal symptoms and the decreased serum prolactin suggests the postulated dopamine hyperactivity is present but not intimately related to generation or relief of symptoms.

Clonidine and the opiates reverse the behavioral effects of electrical or chemical activation of noradrenergic nuclei in primates (9, 10). On the basis of these and other studies we have suggested that opiate withdrawal results from increased neuronal activity in noradrenergic brain areas, which are regulated by both α-2-adrenergic and opiate receptors (1). Additional studies that concurrently measure withdrawal symptoms and the major brain metabolite of norepinephrine, 3-methoxy-4-hydroxyphenylglycol (MHPG), during spontaneous opiate withdrawal and after clonidine administration are necessary to determine whether the postulated noradrenergic hyperactivity (1) for opiate withdrawal is present (i.e., increased MHPG) and related to symptom relief (i.e., return to nonwithdrawal baseline levels after clonidine administration).

Saliva Lithium and Lithium Therapy

BY ROY J. MATHEW, M.D., JAMES L. CLAGHORN, M.D., DAVID FENIMORE, PH.D., CHESTER DAVIS, PH.D., AND MAXINE WEINMAN, PH.D.

The substitution of saliva lithium measurements for the accepted serum assays in the monitoring of lithium therapy has been a topic of recent interest (1–3). Despite the consistently high correlation between saliva and plasma lithium levels, it has been indicated that individual variability is too high to permit the clinical use of saliva assessments as a valid measure of lithium levels (2). In addition, the reliability of plasma lithium values as an index of lithium activity has also been questioned, and it has been suggested that red blood cell (RBC) lithium levels may be a better index of lithium activity (4–7).

This study evaluated the relationships among plasma, RBC, and saliva lithium levels using atomic absorption spectrophotometry.

Method

Thirty synchronous samples of blood and saliva were taken from nine subjects at varying stages of lithium therapy after the procedure was explained and their informed consent obtained. All samples were collected in the morning before the initial daily dose of lithium was taken. The patients rinsed their mouths four times with tap water and chewed a piece of paraffin wax for 3–4 minutes; they were instructed to swallow the saliva produced during this period. They were then instructed to spit into a container several times until 2–3 ml of froth-free saliva was collected. If the sample was not clear, colorless, and froth-free, the procedure was repeated until an acceptable sample was obtained.

Assay procedures. Lithium levels were determined in saliva, plasma, and erythrocytes on an atomic absorption spectrophotometer. The intracellular level of lithium was determined by the method of Hisayasu and associates (8).

The lithium concentration within the erythrocyte was calculated from values in whole blood, plasma, and the hematocrit. In order to verify results, all samples were assayed in duplicate alongside commercial control samples.

For the lithium measurements, plasma, whole blood, saliva, and standard were diluted 10-fold with deionized water; this mixture was aspirated directly into the flame of the spectrophotometer.

Results

Pearson product-moment correlations were calculated between saliva lithium and plasma lithium levels ($r=.569$, $p<.001$), saliva lithium and RBC lithium levels ($r=.501$, $p<.01$), and RBC lithium and plasma lithium levels ($r=.597$, $p<.001$). A high degree of individual variability was noticed when saliva lithium levels were plotted against plasma lithium and RBC lithium. Intraindividual variations in the ratios of saliva and RBC, saliva and plasma, and plasma and RBC lithium levels were also found to be high. No significant correlations were found among these three ratios.

Discussion

Our finding confirms that of Sims and associates (2), i.e., saliva lithium levels have limited usefulness in monitoring lithium therapy. We found a high correlation between the plasma and saliva lithium values, but there was an unacceptably high interindividual and intraindividual variation. Saliva lithium showed a stronger correlation with plasma lithium than RBC lithium; a high degree of scatter was seen when RBC lithium was plotted against salivary lithium. Even if one accepted the viewpoint that RBC lithium levels are a better index than plasma levels for the monitoring of lithium therapy, saliva lithium assessments would still be of limited use.

IN MEMORIAM

H. Houston Merritt
1902–1979

H. HOUSTON MERRITT, M.D., Dean Emeritus and Vice President Emeritus in charge of Medical Affairs and Emeritus Professor of Neurology, College of Physicians and Surgeons, Columbia University, died on January 9, 1979, three days before his 77th birthday. Despite an incapacitating gait disorder, he was active to the end, having just completed the sixth edition of his famous *Textbook of Neurology*, which is regarded as a standard text throughout the neurologic world.

Dr. Merritt graduated from Johns Hopkins Medical School in 1926. After training in medicine at New Haven Hospital, he went to Boston City Hospital in 1928 for training in neurology. There he joined a brilliant group of clinical researchers and by 1938 his name had appeared on 55 papers, some in collaboration with men of the caliber of Solomon, Frank Fremont-Smith, Moore, and Lenox. In 1939 he collaborated with Tracy Putnam in the discovery of phenytoin (Dilantin) as an anticonvulsant—a godsend to sufferers of convulsive attacks. At the same time Dr. Merritt became known as an authority on cerebrovascular diseases and on cerebrospinal fluid. Ironically, his final illness included disorders in both of these areas.

Meanwhile, Dr. Merritt had risen to the rank of Associate Professor in Neurology at Harvard Medical School. In 1944 he was called to New York. First he was Clinical Professor and Chief of the Montefiore Service, Columbia University, and then in 1948 became Professor and Chairman of the Department of Neurology at Columbia and head of the New York Neurological Institute. Ten years later he was elected Dean and Vice President of Medical Affairs at Columbia while he still retained his position as Director of the Neurological Institute.

Under his direction, the Neurological Institute became a major training center for clinical neurology and neurologic research. The William Black Research Building was erected in 1960 and a short time later the medical school affiliated with the Harlem Medical Center—both events under Merritt's aegis—and thus his university demonstrated its commitment to research and to the care of the not-so-fortunate.

In recognition of his many achievements the Merritt Chair of Neurology was dedicated in his honor, as was the Merritt Clinical Research Center for Muscular Dystrophy and Related Diseases. Honors too numerous to mention accrued to him through the years. When he entered neurology it was languishing as a discipline and there was danger that it would be absorbed by medicine and neurosurgery. But, fortunately, he lived to see it attain its present major status—indeed, he is regarded by many as the principal architect in the rise of modern neurology. Always well disposed toward psychiatry and helpful to its cause, Dr. Merritt was a Life Member of the American Psychiatric Association.

Dr. Merritt was a modest man who wore his honors lightly. Many of the honors he received were associated with great responsibilities, yet he carried them out quietly, skillfully, and with éclat. He was called into consultation regarding a President of the United States, a famous Russian official, and the dictator of Portugal. Portugal conferred upon him its highest honor, the title of Grand Officer of the Order of Santiago. Withal he treated the high and the lowly with equal skill and devotion.

An astute and popular clinician and teacher, Dr. Merritt had an intelligence and a remarkable memory that were often commented upon, as was his fabled reputation as a master diagnostician. Indeed he was a bit of a genius, and fortunately his lamp of genius remained lit until near the end of his life. He was a warm, sensitive man—soft-spoken and sparing of speech to the point of being laconic—and people from all walks of life were attracted to him. He cared for people and people in turn cared for him. He could relieve tight situations with a witty remark or an appropriate comment taken from his fund of humorous stories.

He received a number of distinguished service awards from colleges and professional societies. On the occasion of the golden anniversary of the American Neurologic Association (which he helped to bring to full flower) the president of that association, while presenting the award, unwittingly furnished an epitaph for him. He said, "For H. Houston Merritt, Neurologist to the World." This designation is indeed a fitting epitaph for a great man.

Further Perspectives on Primary Prevention

SIR: The article "Primary Prevention in Perspective" (January 1979 issue) by Richard Lamb, M.D., and Jack Zusman, M.D., takes the seemingly paradoxical position which advocates treatment of mental disorders as a first priority and prevention as a separate and secondary activity. The authors argue not that primary prevention is less important than treatment, but rather that it is not scientifically based and virtually impossible to carry out. Although I recognize that there are difficult methodologic problems in evaluating prevention activities, I strongly disagree with the authors' implicit antiresearch position. Although this is by no means a new debate, as one who sees greater possibilities—both theoretically and clinically—for individual and population-based strategies of prevention, I wish to address a few observations to the authors.

First, the studies they cited on the relationship of social factors to mental disorders are indeed largely based on statistical associations, and each has its methodologic limitations. Like all such studies, including research demonstrating relationships between cigarette smoking and lung disease, these studies alone do not prove causation, nor could they be expected to do so. On the other hand, the evidence for the so-called "proven" forms of prevention described in the article, which I would not dispute, is also largely based on statistical observations (e.g., "seldom seen today," "lowered incidence"). Despite complex methodologic differences among studies, the saw cuts both ways. The list of proven preventions can be made much longer than that offered by the authors, as a review of any volume of a good public health journal will reveal. The potential impact of these prevention programs in terms of numbers of persons affected can be very large indeed.

Second, the authors seem to imply that their scientific imagination does not encompass future developments in basic clinical research. Are they certain that the next 10, 20, or 50 years does not hold the promise of effective medical or biological prophylaxis of some psychiatric disorders?

Finally, while I would not disagree with the need to devote a preponderance of resources to the treatment of persons with severe and chronic psychiatric disorders, it does seem unscientific to argue against research on prevention or evaluation of treatment. Research is usually expensive, but the potential payoff is more proven preventions. In a field where treatment produces few "cures," prevention is a valuable source of hope, not a "dangerously foolish gamble."

ROBERT A. DORWART, M.D.
Cambridge, Mass.

SIR: Drs. Lamb and Zusman have correctly identified many of the conceptual and practical problems anent prevention. Prevention programs tend to be popular, cosmetic, and inconsequential (1). In one community mental health program, I observed that growth groups with adequate but unactualized clients receive top priority for a therapist's time, while more intransigent cases are placed on a waiting list or referred elsewhere.

Of course, this is not news. Therapists' proclivities for the YAVIS (young, attractive, verbal, intelligent, and successful) were identified 15 years ago by Schofield (2).

The full irony of the analysis presented by Drs. Lamb and Zusman is that many of their arguments against prevention can be applied equally well to psychotherapy. London (3) quoted the classic definition: "Psychotherapy is an ill defined technique applied to an unknown population with indeterminate results. For this technique, long and arduous training is required." It has held up well.

In psychotherapy, as well as in prevention, there are many theories with little validation. There have been few unequivocal demonstrations of the efficacy of psychotherapy. Perhaps most ironic of all is the authors' insistence that in allocating funds to prevention "we need to distinguish carefully among those programs which are proved, those which are not yet proved but seem well on the way to attain a status, and those which are at best experimental." It seems to me that there are remarkably few mental health programs that meet even the minimal standards of experimental design in the sense of collecting evaluative data and using them for something more than a head-count to justify continued funding.

The authors performed a valuable service by documenting areas where prevention efforts have worked. Those excited by "doing prevention" often overlook these areas and sometimes consider them irrelevant. I think that the dramatic reduction in drug poisonings in children following legislation mandating "child-proof" packaging serves as a good example of prevention, as does the reduction of barbiturate-related suicides that was seen after prescription practices were tightened (4).

I would encourage would-be mental health "preventors" to examine these cases of successful prevention more closely. In fact, I would contend that the most effective and far-reaching prevention will come from increased attention to the role of policy and legislation.

MARK WORDEN, M.D.
Roseburg, Ore.

SIR: I want to comment on Drs. Lamb and Zusman's paper because what is valid and important in it may be obscured by the surprising number of assertions that are simply incorrect or controversial editorializing. I have long admired the work of these two scientist-practitioners and am saddened to see them associated with a point of view that is so parochial and unconstructively negative.

The authors' position is that "there is little evidence that primary prevention has been effective," that "research. . . in prevention is sorely needed but should be funded separately and with descretion," and that "scarce mental health funds should not be diverted from direct treatment for this purpose" (p. 12).

The authors are correct that the need for mental health services now far outstrips the availability of mental health professionals and will probably continue to do so for the foreseeable future. They are correct that the renewed hopes for effective primary preventions have come about, in part, from the increasing realization of this melancholy mismatch between the supply and demand for mental health services. However, I have never heard or read a proposal by any responsible person reflecting "an enthusiastic acceptance of prevention as an alternative to direct treatment" (p. 12). Such an assertion on the authors' part is frank hyperbole and a bit irresponsible. I can assure Drs. Lamb and Zusman that the Task Panel on Prevention of the President's Commission on Mental Health never entertained such a notion.

The authors focus on psychosocial aspects of prevention. They urge the reader to be cautious because the assumption behind much of contemporary thinking about primary prevention—that "difficult life circumstances lead to mental illness," or that "later psychopathology is to be understood in terms of earlier life experiences"—is as yet unproved. It is not clear how the authors have chosen to use the phrase "mental illness" or what they would accept as proof, but I would point out that most of the mental health clinical enterprise rests on that same assumption.

The authors incorrectly stated that "without knowledge of cause, primary prevention programs can only be shots in the dark" (p. 13). The great triumphs of prevention in the field of public health have occurred in the absence of knowledge of cause. Most successful primary prevention programs have been implemented on the basis of suspected associations, not known causes. If Drs. Lamb and Zusman want to argue that suspecting associations between events is the same as knowing cause, then we are in the same position in the field of emotional disorders that we were in with regard to the infectious and nutritional disorders of the past century. We have enough empirically derived associations to undertake a whole series of modest, well-designed experimental intervention programs.

"Recent research has increasingly suggested the operation of genetic and biochemical factors in the production of mental illness, and these factors are not targets of typical primary prevention programs" (p 13). The authors are uninformed in this case. Interest in learning more about genetic and biochemical factors pertinent to primary prevention of emotional disorders is intense and central in the thinking of virtually all persons professionally concerned with primary prevention.

"Recent research . . . indicates that major mental illness is probably in large part genetically determined and is probably therefore not preventable" (p. 13). This assertion would make a geneticist cringe. Huntington's chorea, Tay-Sach's disease, and phenylketonuria are all genetically determined and preventable.

Drs. Lamb and Zusman urge that "prevention's appeal must be resisted by mental health professionals lest it become a glamorous rationalization for avoiding treatment of difficult, mentally ill persons" (p. 16). I share their concern for the chronic difficult patient but, regrettably, mental health professionals have not had to wait for the glamor of prevention to avoid treating such patients. Our professions have a long history of spending most of our clinical hours with the most mildly disturbed individuals.

The recommendations of the President's Commission on Mental Health on the subject of prevention are, in my judgment, prudent, appropriate, and timely. These recommendations—for the establishment of a Center for Prevention within the National Institute of Mental Health, for special programs directed toward children at risk, and for the development of services and programs oriented around times of significant life stress—deserve the active support of all mental health professionals and professions. To insist on waiting until all direct treatment needs are paid for before resources are devoted to prevention efforts is to doom our professions to unending continuation of the hopeless spiral we are in now. Of course, some money may have to be diverted from direct treatment in order to undertake a significant effort in extending our knowledge in the field of primary prevention. In terms of the total cost of mental illness to our society, that resource diversion is not only trivial but, more importantly, represents one of the few hopes we have for the ultimate control of one of our major sources of human suffering.

BERNARD L. BLOOM
Boulder, Colo.

SIR: Drs. Lamb and Zusman should be applauded for their article on primary prevention, which should have been subtitled, "The King Is Naked." They expose the fact that in our current state of the art, no one can deliver on the promise of prevention of psychiatric illness.

In the political marketplace, hollow promises often prevail over hard, and unpleasant, facts. The mental health field is riddled with politically favored programs that pursue laudable goals with unproven and often patently ineffectual means. We need more articles debunking popular myths. Efforts will be better spent on serious research that will someday provide answers than on present-day equivalents of snake oil. The article by Drs. Lamb and Zusman is a step in the right direction.

JOSEPH MORE, M.D.
Wilson, N.C.

Drs. Lamb and Zusman Reply

SIR: The purpose of our article "Primary Prevention in Perspective" was to direct attention to the fuzziness of many

of the concepts and definitions involved in primary prevention and to focus on some of the complex issues that are often glossed over in looking for the elusive "ounce of prevention."

Dr. Dorwart has misperceived our position on prevention as "antiresearch." No one feels more strongly than we about the need for research in this area. We would only reiterate that we think this research should be funded separately, with a full understanding of the issues, that it consist of carefully controlled studies, and that it not be at the expense of reducing direct services. Further, we feel that wide-scale "prevention" programs should not be set up until there is good research evidence that they are effective.

Unlike Dr. Bloom, we are well aware of responsible persons who reflect "an enthusiastic acceptance of prevention as an alternative to direct treatment." This was especially true in the '60s and early '70s, when it was often implied (and sometimes promised) that the techniques of prevention would result in a significant reduction of mental illness and would eventually drastically reduce the need for conventional treatment because there would be so few patients (1, 2). More recently, advocates of prevention have been just as enthusiastic but more careful in their wording.

We hope that Dr. Bloom is not correct when he states that the entire mental health clinical enterprise rests on the assumptions that difficult life circumstances and social conditions lead to mental illness (when we use that term we refer to diagnosable mental illness) or that later psychopathology, including the psychoses, is to be understood in terms of earlier life experiences. The convincing evidence of the past decade that there are genetic factors in the etiology of schizophrenia, the primary affective disorders, alcoholism, and antisocial personality should cause us to consider modifying some of these assumptions and take these genetic factors into full consideration (3–5).

We stand by our statement, "Without knowledge of cause, primary prevention programs can only be shots in the dark." Of course, even shots in the dark will occasionally hit the mark, and there are notable instances of this in the history of public health. But with all the pressing demands for scarce mental health funds and the tremendous complexities and intangibles in the area of mental health, how many millions of dollars can we afford for such long shots?

We are pleased to hear from Dr. Bloom that "interest in learning more about genetic and biochemical factors pertinent to primary prevention of emotional disorders is intense and central in the thinking of virtually all persons professionally concerned with primary prevention." We hope this attitude becomes more prevalent, for to date such persons are in the minority of those advocates of prevention who make their views known publicly. For example, the lack of discussion of such factors was notable in the report of the Task Panel on Prevention of the President's Commission on Mental Health, in which Dr. Bloom was involved. Further, genetic counseling that has the potential for preventing mental illness seems to be only of peripheral interest to most of those involved in prevention efforts.

We want to thank Dr. Worden for pointing out the need for meaningful evaluation of all mental health services and Dr. More for his encouragement of our efforts.

Defending the Military Family

SIR: "The Military Family Syndrome" (September 1978 issue) by Don M. LaGrone, M.D., which painted an unfavorable picture of the military family, was based on a number of false and/or misleading analyses of statistics. Since the damage done by this article has been magnified considerably by its quotation in *Time* magazine (Dec. 11, 1978) and in *Air Force Times* (Dec. 25, 1978), I feel it incumbent on me and the Air Force to correct Dr. LaGrone's analysis.

Dr. LaGrone stated (p. 1043) that "the incidence of child abuse is five times higher than the national rate." In fact, the USAF *Medical Service Digest* article he used as a source said, "Some studies indicate that our mortality rate could be as much as five times the national average figures." This comment was based on a study done before the Air Force started collecting comprehensive data on child abuse; since the implementation of the Air Force Child Advocacy Program in 1975, the actual figures collected indicate that the overall incidence rate of child abuse in the Air Force is about the same as in the nation at large, and the mortality rate from child abuse is lower in the Air Force. In 1976 the incidence of child abuse/neglect cases among Air Force families was reported to be 392 per million, with a mortality rate of 1.8%. In 1977 the number of cases dropped to 336 per million, but with a mortality rate of 2.5%. In 1974 among U.S. civilian families the incidence of child abuse/neglect cases was reported as 380 per million, with a mortality rate of 5%.

Dr. LaGrone said that "the incidence of alcoholism is high" (p. 1043). Contradicting this assertion, a 1978 Rand Corporation study (available in draft) states that "alcohol-related behavior in the Air Force is similar to that among civilians."

Dr. LaGrone miscalculated and misinterpreted the figures on psychiatric treatment of children of military members (p. 1040). If we accept Dr. LaGrone's premise that there was an entirely new group of 3,200 families on base each of the 2 years, then the parallel figures for children would be 14,800 in 2 years, not 12,800. Of the 14,800 children, 5.35% (N=792) were seen for evaluation. Since 6% of these (N=48) had no psychiatric diagnosis, the number potentially needing help was 744, or about 5% of those on base. If we accept Dr. LaGrone's estimate that "10% to 12% of the general population of children in the United States have emotional problems and need treatment," it appears that the military children have much less need—5% versus 10%-12%. Finally, the catchment population for the military clinic that Dr. LaGrone used as a basis for his statistics was understated since the hospital and its clinic drew from a regional population.

This would further lower the incidence of mental illness in military children.

Contrary to Dr. LaGrone's statement that "when confronted with such information (alcohol and child abuse incidence) the military becomes defensive and moves slowly, if at all" (p. 1043), the Air Force is among the leaders in establishing human service programs to help individuals and families deal with alcohol and child abuse problems. The first Air Force alcohol treatment center was established in 1966 at Wright-Patterson Air Force Base, Ohio. The Air Force Child Advocacy Program was launched in April 1975 and has been highly effective.

GARTH B. DETTINGER, MAJ. GEN., USAF, MC
Deputy Surgeon General
Washington, D.C.

Dr. LaGrone Replies

SIR: Gen. Dettinger's letter is difficult to address specifically, since he entirely missed the point of my paper. He chose to attack two side issues I raised in my closing comments and on that basis claimed my conclusions were erroneous. In my opinion, he wrote his letter for a political purpose rather than in the spirit of scientific debate.

I am struck by the drastic drop in the mortality rate of military child abuse he reports since 1975. I cannot help but be skeptical and invite Gen. Dettinger to quote the source of his statistics. A recent study summarized by the *Houston Post* (January 22, 1979, p.9a) stated that the incidence of military child abuse is two to three times higher than the civilian rate. A study mentioned in that review compared the incidence of child abuse at Fort Carson, Colo., with the local civilian population and found it twice as high. The Rand Corporation study quote Gen. Dettinger used says nothing about the significance of drug and alcohol abuse in the military. The "behavior" probably is the same. While in the military I attended a lecture given by an Air Force social actions instructor who said that 80% of all students and new recruits were abusing drugs.

Regarding the clinical statistics in the paper, there was a mistake in the number given for children living on the base. It should have been 6400 instead of 7400. I based this on the personnel office estimates of 2 children per family. I believe the rest of the numbers given in the paper are correct. I think the fact that we evaluated almost 12% of the children over 2 years of age is notable, especially in view of the resistance in officers' families to mental health involvement. The fact that our base was regional has no bearing on our study since, almost without exception, the families resided on the base.

The purpose of my paper was twofold: to explain the higher incidence of behavior disorders in children evaluated in our clinic as opposed to civilian clinics and to help the nonmilitary therapist understand the dynamics of the military family and the military. To effect positive change, the therapist must also consider the identified patient as part of a very complex "system."

Two other studies, those of Bloom (1) and White (2), were similar to mine. White, in fact, reported that 59% of his diagnoses were behavior disorders and attributed the cause to similar dynamics.

In my response to Dr. Jon Shaw's letter (3), I explained that I first tried to publish my paper while in the military. It was rejected in "official channels" eight times. Finally I was told that it would not be cleared because "it would hurt the recruiting program." How valid is research derived from a system that represses "unofficial" points of view? When considering the dynamics of such a system, I would suggest that Gen. Dettinger's use of the word "damage" in reference to the impact made by clinical research could be viewed as pathognomonic.

DON M. LAGRONE, M.D.
Beaumont, Tex.

Reserpine, Serotonin, and Schizophrenia

SIR: The improvement of some chronic schizophrenic patients with the addition of reserpine to their neuroleptic regimen as reported in "Addition of Reserpine to Antipsychotic Medications in Refractory Chronic Schizophrenic Outpatients" by Norman M. Bacher, M.D., and Harvey A. Lewis, M.D., (April 1978 issue) is a clinical finding that we have observed repeatedly over the past two years.

Our clinical (uncontrolled) trials with reserpine produced a tangible and sometimes marked improvement in certain chronic schizophrenic patients who for years had not responded fully to various neuroleptics of the dopamine (DA) receptor-blocking type. We also observed that chronic schizophrenic patients with prominent psychomotor agitation, auditory hallucinations, and paranoid schizophrenia (chronic paranoid schizophrenia or schizo-affective schizophrenia, excited type) tended to respond better to reserpine than chronic schizophrenic patients with negative symptoms such as withdrawal-retardation, flat affect, and anhedonia.

Because reserpine depletes the stores of serotonin as well as dopamine, norepinephrine, and other catecholamines, the authors raised the question of whether there is an increased activity of serotonin in chronic schizophrenia. The question has of course been raised repeatedly in the literature of the past two decades, and researchers still do not agree (1) on whether serotonin activity is increased or decreased in schizophrenia; there is evidence for both possibilities.

One of our severely psychotic patients who achieved his best remission in over 12 years with the addition of reserpine (10 mg/day) to his neuroleptic (chlorpromazine, 1600 mg/day) had previously become worse with the addition of the serotonin precursor 5-hydroxytryptophan (5-HTP) (up to 2700 mg/day with peripheral decarboxylase inhibition) (2). He had also shown no improvement with the addition of the dopamine synthesis inhibitor α-methyl-*p*-tyrosine (AMPT) (up to 3000 mg/day) (3). His response profile is consistent with an increase in serotoninergic activity in schizophrenia. The patient also had a low platelet MAO activity, which is compatible with an increase in serotonin (4). Platelet MAO activity has been reported to be lower in chronic paranoid schizophrenics with auditory hallucinations (the type of schizophrenia we noted to be reserpine-responsive) than in other chronic schizophrenic patients (5).

It is possible that a certain subtype of chronic schizophre-

nia characterized by increased psychomotor agitation, paranoid delusions, and prominent auditory hallucinations, with partial or no response to dopamine-receptor blocking neuroleptics, and showing clinical improvement with the addition of reserpine, could have increased CNS serotoninergic activity with or without increased dopaminergic activity. Such a subtype would 1) have low platelet MAO activity, 2) worsen with serotonin agonists, and 3) (theoretically) benefit from a trial of serotonin antagonists like para-chlorphenylalanine (PCPA). An opposite schizophrenic subtype could exist, characterized by negative symptoms like autism, flat affect, and minimal agitation or auditory hallucinations. Patients in this group could have low CNS serotoninergic activity (with or without dopaminergic hyperactivity), high platelet MAO activity, partial or no response to dopamine receptor blocking neuroleptics, worsening with reserpine or PCPA, and improvement with serotonin precursors such as 5-HTP (2).

Such hypothetical subtypes of chronic "neuroleptic-resistant" schizophrenia would not only explain the response to reserpine but reconcile the confusing literature on serotonin and schizophrenia.

Decision-Making Approaches in Medicine

SIR: We were disappointed in the uncritical approach to decision tables taken by Bruce Roberts, M.D., in "A Look at Psychiatric Decision Making" (November 1978 issue). Dr. Roberts correctly noted that decision tables have existed for a long time and that a great deal is known about their properties (1). We believe that these properties make decision tables unsuitable as a means of representing algorithms for all but a small group of medical decisions. There are three major sources of difficulty:

1. There is neither an optimum nor a systematic way to order decisions (e.g., in figure 2, p. 1386, of the article one might argue that ruling out organicity should take precedence over determining the presence of a normal grief reaction, since neither precludes the other), and the order selected has a significant impact on the amount of effort required to use decision tables (1). Depending on the sequencing of items, there can be an order of magnitude variation in the number of questions that a user must answer to reach a decision. A constructor of decision tables is often faced with the unacceptable alternatives of building tables that are either medically optimum but contain too many items or are mathematically optimum but medically less sensible.

2. There are some simple decision rules that are easy to state but difficult to express in a decision table. An example is the rule used in the current draft of *DSM-III* to conclude whether a patient is suffering from a depressive episode. The rule requires that, among other things, 4 out of 8 symptoms be present. In a decision tree there is no way to directly express this "4 out of 8" consideration before taking an action.

3. There is no meaningful way to handle uncertain or imprecise information. In Dr. Roberts' example of the ancient Persian poem (p. 1384–1385), what is one to do when one is uncertain whether one knows? If one cannot give a yes or no answer after exhausting all sources of information in a clinical situation, what is the procedure to take when one reaches a point that allows only a yes or no answer?

For these reasons, we feel that, even as pedagogic devices, decision tables are unattractive. There are other approaches, such as production rules (2) or decision sets (3), that have all of the power of decision tables and fewer drawbacks.

We share Dr. Roberts' opinion that formalizing medical decision making is an important task. It is also a complex and difficult task. Why attempt it with inadequate tools?

RUVEN E. BROOKS, PH.D.
JON F. HEISER, M.D.
Galveston, Tex.

Dr. Roberts Replies

SIR: Drs. Brooks and Heiser state, "There is neither an optimum nor a systematic way to order decisions. . . ." I disagree. There are times when one decision has a higher priority than another decision. Whether a depressed patient is an immediate danger to self or others should be assessed before a decision is made to use antidepressant medication. There are times in the decision-making process when there is no optimum next decision. This uncertainty can be incorporated into a systematic approach. An example of this is whether to first investigate for organic causes a depression with vegetative symptoms or to first treat this depression with an antidepressant. There are no consistent data on the percentage of positive findings of organic illness by age as a cause of depression with vegetative symptoms. In light of this uncertainty, many approaches are acceptable. One could empirically treat the depression with antidepressants and then look for organic causes if the antidepressant does not totally improve the symptoms. Another approach would be to look first for organic causes of the depression. If no organic causes are found or treating the organic causes only partially improves the symptoms, then antidepressants can be tried. Multiple combinations of looking for organic causes and treating with antidepressants can be tried. This flexibili-

ty can be incorporated into a systematic approach and is being done by Weed (1) and Schultz in the Problem-Oriented Medical Information System (PROMIS) Laboratory.[1] The PROMIS system allows for multiple choices on one display. In the above example, the computerized problem-oriented record would allow the user the freedom to investigate one or more organic causes and/or empirically treat the patient with antidepressants. There are many times in psychiatry, even if all the knowledge is available on a given subject, when there is no clear direction to take. A decision must be made in the face of uncertainty. This uncertainty can and has been incorporated in the computerized problem-oriented record.

Drs. Brooks and Heiser state that "in a decision tree there is no way to directly express this '4 out of 8' consideration before taking an action." In my original manuscript there was a decision requiring "5 out of 8" to be present to help decide if medication was indicated, and I have sent Drs. Brooks and Heiser a copy of the manuscript. There is no difficulty incorporating this type of decision in a decision table. There is also no difficulty providing a "not sure" option along with the yes or no option.

I think it is crucial to understand clearly what decisions are being made and how we are making them. I think Drs. Heiser and Brooks share my enthusiasm for objectifying the decision-making process. The underlying question is how this work will be computerized and how it will assist psychiatrists. My bias is that the goal should be to develop a system to organize information and provide a logical structure for making clinical decisions—not to replace the psychiatrist's ability to think. This system would relieve the psychiatrist from memory-oriented tasks and allow him or her to focus on the more difficult tasks of incorporating empathy and understanding into the decision-making process.

A Plea for Consistent Terminology

SIR: In "Psychotherapy of the Medically Ill" (January 1979 issue) Toksoz B. Karasu, M.D., used inconsistent terminology and limited conceptualization. Although he was dealing with the status of psychotherapy in general, he restricted his scope to psychosomatic conditions with the exception of a report on group therapy for postmyocardial patients.

Dr. Karasu omitted several important groups of patients. For many years liaison psychiatry has been involved in the diagnosis and treatment of psychiatric conditions that do not have psychosomatic etiologies. It has also dealt with sequelae of medical and surgical interventions and their impact on the psyche. Psychiatric support and psychotherapy for cancer patients are relatively new and important areas of psychiatric intervention that are missing from Dr. Karasu's review. Another important area excluded from the review is psychological management of the chronically ill and physically handicapped patient. Dr. Karasu also left out treatment of the child with congenital and chronic illness.

Psychotherapy results are generally more encouraging for medically ill patients who do not suffer from psychosomatic conditions than Dr. Karasu indicated. Examining both groups as controls might shed light on the different defense mechanisms these patients use.

Making "medically ill" synonymous with "psychosomatic" adds to confusion in a field where conversion symptoms, imaginary ailments, malingering, and psychosomatic conditions are often poorly defined and used interchangeably by many practitioners.

YEHUDA NIR, M.D.
New York, N.Y.

Dr. Karasu Replies

SIR: I share Dr. Nir's concern about the terminology and scope of my paper "Psychotherapy of the Medically Ill." I intentionally selected the rubric "medically ill" because the term "psychosomatic" and the range of conditions within its purview are either restrictive or unclear at this time, an issue which reaches the heart of the current psychosomatic matter. A broader or less anachronistic terminology tends to promise more than it can deliver, since the controlled investigations I focused on still dwell disproportionately on the more classical psychosomatic disorders. My article was not nearly as confined to psychosomatic conditions as Dr. Nir claims; it included studies, albeit limited, of patients with chronic pain, migraine headaches, those who had undergone ileostomy surgery, menopausal women, patients with anorexia nervosa, and problems of obesity, all of which do represent active trends away from the most orthodox disorders.

Dr. Nir faulted the term "medically ill" for being too broad for its anticipated content. Ironically, he endowed the term "psychotherapy" with a breadth never intended. The introduction of some of the fine work that has been accomplished in the field of liaison psychiatry was an overextension, I feel, of the more structured practice of psychotherapy. By psychotherapy I meant certain specified forms of psychological intervention practiced today, on which the paper clearly pivoted. I never hoped to encompass all forms of psychological care (which would certainly make another article in itself). However, this delimitation was in no way meant to undermine the advances that this growing branch of psychiatry continues to make.

Dr. Nir placed in bold relief the fact that definitions of such complex domains as "psychosomatic" and "psychotherapy" need clarification and are, fortunately, still open to discussion and debate. I am indeed interested in locating any systematic studies of the efficacy of psychotherapy for illnesses other than those mentioned, especially if, as Dr. Nir claims, outcomes for such populations have been more encouraging than the ones I presented.

TOKSOZ B. KARASU, M.D.
Bronx, N.Y.

Nutmeg and *Epená* Snuff: Differing Hallucinogens

SIR: In "Spice Cabinet Intoxication" (July 1978 issue) Robert A. Faguet, M.D., and Kay F. Rowland, Ph.D., de-

scribed the symptoms of a 19-year-old student who experienced self-intoxication with nutmeg.

These writers made two erroneous statements in their attempt to elucidate the cause for the near-hallucinatory condition of the patient. First, they stated that "myristicine" (myristicin) is the psychoactive ingredient of nutmeg (*Myristica fragrans*). No evidence in the scientific literature supports this statement. Indeed, a number of workers have attempted to identify the active principle, all without success.

The second error was a direct quote from Margaret Kreig's book *Green Medicine* (1, pp. 99–100) which described *epená* snuff intoxication as experienced by Professor Richard Evans Schultes. While the quote is correct, Faguet and Rowland indicated that these were symptoms of "myristicine intoxication via snuffing." In fact, there was no myristicin in the *epená* snuff that Schultes used. The snuff is prepared in South America from any one of several *Virola* species; *Virola* is classified in the plant family *Myristicaceae*. Schultes often refers to these materials as "Myristicaceous" snuffs, which apparently confused Faguet and Rowland. The active hallucinogens in *Virola* species (and *epená*) are derivatives of 5-hydroxytryptamine, which under normal circumstances would have no effects when used orally. How the natives discovered that the hallucinogenic effects of *epená* snuff could only be derived through nasal inhalation and not by taking the material orally remains a mystery.

Thus any resemblance between nutmeg intoxication and the effects described by Schultes and others following *epená* inhalation must be considered purely coincidental, and surely not caused by the same chemical compounds.

NORMAN R. FARNSWORTH, PH.D.
Chicago, Ill.

Drs. Faguet and Rowland Reply

SIR: Professor Richard Evans Schultes (1) was our source for the disputed statement that myristicine is the psychoactive ingredient in nutmeg and *yakee* snuff (*epená*, *Virola*). He wrote: "The active principle is undoubtedly the same essential oil—*myristicine*—that is common throughout the family and makes our household nutmeg a dangerous narcotic when used in the appropriate amounts" (p. 107).

Apparently Schultes (2) later emended this view with respect to *yakee*. His later belief supports Dr. Farnsworth's comment that a tryptamine derivative causes the snuff's hallucinogenic effects. But tryptamines alone are ineffective in the human body. To produce a psychotomimetic effect, they must be taken with a monoamine oxidase inhibitor. According to Schultes (2), the B-carbolines, added to *yakee* in the preparation process (the *yakee* resin is mixed with the ashes of any of several MAOI-containing plants), act as monoamine oxidase inhibitors and allow tryptamine to produce its psychoactive effects.

While Dr. Farnsworth wonders how natives discovered that the hallucinogenic effects of *yakee* could be derived only through nasal inhalation, Dr. Schultes asks how "peoples in primitive societies, with no knowledge of chemistry or physiology, ever hit upon a solution to the activation of an alkaloid by a monoamine oxidase inhibitor" (2, p. 38).

Dangerously High Doses of Haloperidol

SIR: The case report "Sudden Death in a Patient Taking Haloperidol" by Richard Ketai, M.D., and associates (January 1979 issue) was of special interest to me. I am not surprised that haloperidol was recently implicated in the sudden death of a 35-year-old mother of three. Increasing numbers of patients are being treated by rapid tranquilization with neuroleptic dosages that are much higher than generally found necessary. Indeed, the relative absence of α-adrenergic blockade and anticholinergic properties renders haloperidol a uniquely safe and effective antipsychotic agent for the acute patient. However, during the past year I have been concerned about the number of psychiatrists who administer 200–300 mg of haloperidol in 24 hours to acutely agitated and psychotic patients, viewed as "resistant" to much smaller dosages.

In our pilot study using haloperidol in the treatment of acute psychosis, we observed two distinct groups of patients: those whose psychosis and agitation responded to 40–60 mg of haloperidol given during the first 24 hours, and those occasional patients who clearly did not respond (1). For this latter group, the addition of amobarbital sodium, 500 mg I.M., to the haloperidol regimen proved consistently effective in relieving both psychosis and agitation while limiting the need for additional neuroleptic medication.

Since that time my clinical experience has repeatedly demonstrated that the combination of haloperidol and amobarbital sodium is dramatically effective and safe for acute psychotic patients. Further, this combination limits the dosage of the antipsychotic and avoids dystonic reactions. The merits of the rapid tranquilization technique are well documented. Modifying this technique in the context of safety remains a worthy objective for us all.

WILLIAM E. THORNTON, M.D.
Charleston, S.C.

Dr. Ketai Replies

SIR: I share Dr. Thornton's concern about very high doses of haloperidol. For the majority of acutely psychotic patients dosages of more than 60 mg of intramuscular haloperidol in 24 hours provide diminishing returns in respect to the likelihood of response. Occasionally, a patient will respond for the first time at doses greater than 100 mg/day, but potential

risks at these high doses suggest consideration of alternative approaches. For example, three patients on our ward recently complained of sudden respiratory distress and gagging while being treated acutely with standard doses of haloperidol. We noted these cases in light of the current report by Flaherty and Lahmeyer (1) about haloperidol-induced laryngeal-pharyngeal dystonia. We do not know whether higher doses of haloperidol would make this potentially dangerous side effect more likely to occur, but it would be wise to exercise caution for now. Our patients who had this side effect, like those previously reported, responded immediately to intravenous diphenhydramine.

Dr. Thornton's report of an enhanced antipsychotic response to 500 mg of intramuscular amobarbital sodium added to haloperidol in refractory patients is intriguing. We have used secobarbital and amobarbital in doses of 100–300 mg I.M. every 6 hours for several haloperidol nonresponders but have not been impressed by an increased antipsychotic response with this combination. If Dr. Thornton is correct this could be explained by an inadequate barbiturate dose. We do have better results by switching to a different neuroleptic, usually chlorpromazine, if the acutely psychotic patient has not responded to haloperidol in 3–5 days. Sometimes we observe that the addition of lithium is necessary before an adequate response results. This procedure should definitely be considered if mania has not been ruled out.

A study focusing on treatment options for acutely psychotic haloperidol nonresponders (at the 60 mg/day level) would be helpful. A blind comparison should at least be made between a switch to chlorpromazine versus addition of intramuscular amobarbital to the haloperidol regimen.

Efficacy of Consultation-Liaison Settings

SIR: We wish to underscore the importance of educational research such as that reported by William W. Weddington, Jr., M.D., and associates in "Consultation-Liaison Versus Other Psychiatry Clerkships: A Comparison of Learning Outcomes and Student Reactions" (December 1978 issue). Reifler and Eaton (1) have pointed out the lack of outcome studies in this area.

The Weddington and associates article demonstrates that the consultation/liaison setting is at least as effective as more traditional psychiatric settings when performance on standardized testing is used to measure learning outcome. In our own health care center, during the June 1977–July 1978 academic year 19 students rotated through the consultation/liaison service, while 113 were assigned to one of six inpatient services or an emergency room service. All students then viewed a videotaped clinical interview, and their clinical knowledge was individually rated by oral examination as fail, low pass, high pass, or honors. Consultation/liaison students were more frequently rated as achieving high pass or honors status than students on other services ($\chi^2=8.88$, $df=3$, $p<.05$). There were no significant differences in the low pass and pass categories. No students failed. Since students were not randomly assigned to their clinical rotations, these results are necessarily biased. Nevertheless, they are suggestive.

The Report of the President's Commission on Mental Health, which indicated that over 50% of psychiatric care is delivered by nonpsychiatrists, suggests that most psychiatric care may continue to be delivered in traditional medical settings (2). The consultation/liaison setting may, therefore, be a particularly meaningful one for educating students who do not plan to specialize in psychiatry, since it emphasizes medical-psychiatric integration.

Long-term outcome studies are needed to assess the effectiveness of various psychiatric settings in educating medical students, especially those who do not specialize in psychiatry.

Meta-Janusian Thinking

SIR: In his interesting paper, "Einstein's Creative Thinking and the General Theory of Relativity: A Documented Report" (January 1979 issue), Albert Rothenberg, M.D., helps clarify the nature of scientific creativity, which he views as the product of active secondary process thinking, during which "Janusian thinking" takes place. Here, the formulation of simultaneous opposite ideas results in a creative discovery, an example of which is the theory of relativity, in which Einstein reconciled an apparent contradiction—that an object standing still could be moving at the same time. Dr. Rothenberg emphatically states that Janusian thinking, which also occurs in literary and artistic creativity, is not prelogical, illogical, or "schizophrenic" thinking.

Nevertheless, it is striking how remarkably similar Janusian thinking is to one of Bleuler's primary symptoms of schizophrenia, ambivalence. This poorly understood concept is described as the simultaneous expression of opposite ideas or feelings (1). In addition, illusory feelings of creativity and inspiration are often reported by individuals with functional psychoses and users of hallucinogens, who can become preoccupied with the contradictions of the universe. In such circumstances, however, the lack of an intact ego seems to diminish creativity (2, 3), as can be seen in the works of Van Gogh, whose talent deteriorated during his psychotic disorganization (2).

Is there really no connection whatsoever between simultaneous opposite thoughts that result in creativity and those which result in an illusion of creativity? Perhaps Janusian thinking itself is Janusian in nature. If so, then this very creative, sophisticated, and logical type of thinking would at the same time be regressive, childlike, and illogical.

To reconcile this contradiction of paradoxical thinking, a hypothesis that incorporates cognitive development, such as the following, might be helpful: The retention of certain preoperational (4) thought patterns into adulthood enables them to be activated during both psychosis and Janusian thinking. In psychosis they are fragmented and appear bizarre and pseudo-creative. In Janusian thinking, they are harnessed in the service of secondary process and result in creativity and sophisticated cognition. (Such thinking could have evolutionary implications.)

In summary, the inherent magical thinking of the child, who quite easily tolerates contradiction of logic, might be the common denominator of both Janusian thinking and Bleuler's ambivalence.

Charlottesville, Va.

Dr. Rothenberg Replies

SIR: In my forthcoming book (1), I discuss the relationship between Bleuler's ambivalence and Janusian thinking. Briefly, Bleuler described three types of ambivalence in schizophrenia: affective ambivalence, ambivalence of will, and intellectual ambivalence (2). It is difficult, as Bleuler himself pointed out, to draw hard and fast distinctions among these types. By and large, the term "ambivalence" is now used only to refer to the types involving affect or will, which are virtually indistinguishable. Although we seldom refer to intellectual ambivalence, it does appear in schizophrenia and, although superficially resembling Janusian thinking, it is markedly dissimilar.

When the schizophrenic patient displaying intellectual ambivalence says, "I am a human being like yourself, but I am not a human being" (Bleuler's example), he is not using Janusian thinking because he is not aware of the impossibility of the statement. He neither recognizes the contradiction nor intends the remark to be taken figuratively; he believes it to be true literally. As with primary process thinking, opposites are considered equivalent. One of the reasons for this is that schizophrenic persons seem to have difficulty in forming conceptual categories (3). As opposites are similar to each other in many respects, despite their essential sharp difference and contradiction, the schizophrenic person tends to categorize them together on the basis of the immediately perceived superficial similarity. As for the affective or will type of ambivalence, it differs from Janusian thinking in the lack of conceptual simultaneity of opposition. One does not consciously experience love and hate simultaneously—it must be inferred by him, and by others, from his behavior.

Nevertheless, I think Dr. Brenner's suggestion that there is a developmental connection between the cognition of creativity and that of psychotic or regressive thinking, the "illusion of creativity," is valid. In my research with highly creative writers, artists, and scientists, I have collected a great many data indicating a particular similarity between the backgrounds of creative and psychotic people. Both tend to come from family circumstances in which there is seriously distorted parent-child communication. Both are required to cope with verbal and nonverbal incongruities, and both learn to attend more carefully than other children to subtle and overt aspects of parental communication. The incidence of frank parental psychosis is high in both groups. An important difference is that there is seldom frank psychosis or severe psychiatric illness in both parents of the creative person. In a large number of the cases I have studied, psychosis or severe disturbance in one of the parents is rather strongly balanced by a relatively healthy mate. The prototype for this family structure has, in fact, been immortalized in an extremely creative playwright's well-known drama about his own life, "Long Day's Journey Into Night," in which O'Neill poignantly documented his experience with severe family communication difficulties and a seriously disturbed parent.

Psychotic and creative persons seem to be exposed to similar forces that require them to question and even to ignore the fundamental tenet of ordinary logic that something cannot be both true and not-true at the same time. The creative person, however, is able to espouse seemingly illogical Janusian constructs with clear rationality because of developmental experience with the healthy logic of an intact parent. Thus, psychotic and creative thinking are related developmentally and at times appear similar on the surface. I must, however, correct Dr. Brenner on some particular points. Einstein did not say that "an object standing still could be moving at the same time," but that an observer in motion would be at rest at the same time. In this case, the opposites involved are not symmetrically reciprocal—stationary objects do not, in Einstein's formulation, move. Also, Janusian thinking does not involve the "harnessing" of regressed, primitive thought. That would be similar to the idea Ernst Kris (4) proposed in his famous concept of creativity as "regression in the service of the ego." Janusian thinking instead is a form of high-level cognition at the very moment of its activation, radically and dramatically different from—although superficially resembling—primitive and regressive conceptualizing.

A New Form of Polypharmacy?

SIR: Daniel S.P. Schubert, M.D., Ph.D., has presented the ultimate case of polypharmacy: the use of bethanechol chloride to counteract anticholinergic effects (blurred vision and dry mouth) in a patient treated with the combination of flu-

phenazine and benztropine mesylate ("Use of Bethanechol Chloride with Phenothiazine: A Case Report," January 1979 issue). He stated that the patient "was given 20 mg of fluphenazine and 8 mg of benztropine mesylate p.o., but because of periodic noncompliance, fluphenazine decanoate, 25 mg I.M., was added." Unfortunately, neither the interval nor the duration of administration is specified (an error that the reviewers should have caught). One can only presume that the dosages of oral medications were per day and the injections were given weekly or biweekly. Might I suggest that the author try the more commonly accepted guidelines for prescribing (1) and consider the following alternatives:

1. When side effects occur with neuroleptics, consider decreasing the dose before adding an antiparkinsonian agent.
2. Use antiparkinsonian agents only as necessary, in the lowest possible doses and for the shortest period of time. Generally, there is little need for long-term maintenance.
3. When noncompliance arises, thoroughly discuss the problem with the patient and look for other alternatives before initiating treatment with long-acting injectable preparations.

In addition, Dr. Schubert's case report leaves the following questions unanswered: Why was this patient treated with benztropine mesylate in the first place, and why was it continued? Why was a dosage of 8 mg necessary when 1–4 mg/day in divided doses is generally sufficient to counteract neuroleptic-induced parkinsonism? Why was the same dosage of neuroleptic necessary if the patient's "psychosis receded"? Why was compliance such an issue if he had previously been "relatively clear between episodes"? How was the diagnosis of chronic schizophrenia made, and was the possibility of an affective disorder considered in light of his illness course? And finally, why add another drug with an additional side effect profile and increase the risk of drug interactions?

DANIEL K. WINSTEAD, M.D.
New Orleans, La.

Dr. Schubert Replies

SIR: Sackett and Haynes (1) gave a weighted estimate of about 50% noncompliance with the therapeutic regimen for patients in all specialties. They then indicated that compliance is even poorer among psychiatric patients than those of other medical specialties. Blackwell (2) discussed side effects as one source of noncompliance. My paper was, as indicated in the title, about the use of bethanechol chloride with phenothiazines. This was an extension of Everett's suggestions (3) on the use of bethanechol chloride with tricyclic antidepressants because both phenothiazines and tricyclics possess anticholinergic activity as a side effect. Thus, my intent was to suggest a way to decrease side effects of phenothiazines when they are of the anticholinergic variety. Such symptoms can be severe and tend to lead to noncompliance. Benztropine mesylate shares the anticholinergic property with the phenothiazines and tricyclics and may produce more severe anticholinergic side effects.

I did not suggest that benztropine mesylate or other antiparkinsonian agents be used for parkinsonian-type side effects with phenothiazines. This I leave to others, such as Klein and Davis (4).

In addition to dealing with noncompliance, physicians should attempt to enhance the functioning and comfort of their patients. When medications are the treatment of choice, side effects should be taken as seriously and treated as vigorously as other syndromes.

Bethanechol chloride is also convenient as a test for elements of an anticholinergic (atropine) psychosis while continuing antipsychotic (or antidepressant) treatment.

With regard to Dr. Winstead's paragraph of questions, publication space is limited. However, I would challenge him to present a case that answers all possible questions.

Another Approach to Hyperpyrexia

SIR: Stephen C. Mann, M.D., and William P. Boger, M.D., did a service in reminding us of the hazards involved in the use of phenothiazines with patients exposed to high temperatures ("Psychotropic Drugs, Summer Heat and Humidity, and Hyperpyrexia: A Danger Restated," September 1978 issue). However, as Peele (1) noted in his letter commenting on their article and a related one (2): "We need to be careful to avoid automatically attributing a patient's hyperpyrexia to medication." He suggested that the diagnosis of lethal catatonia must also be considered. I would like to provide a case where a psychiatric illness, in a rather different way, was the cause of hyperpyrexia.

Mr. A, a 50-year-old man with chronic schizophrenia, was admitted to the hospital on a hot August day in a comatose state with rectal temperatures reported as 106° F. Vigorous measures were instituted and a rapid, extensive evaluation that included complete blood studies, a lumbar puncture, EEG, and CT scan revealed no specific etiology for the loss of consciousness other than the temperature. It was assumed at the time that the fever was due to heat stroke secondary to the combination of a phenothiazine and an antiparkinsonian agent (which were known to have been previously prescribed) resulting in faulty thermoregulation on a very hot day.

However, once the patient regained consciousness and his son became available for interview, it was learned that Mr. A had not taken his medication in months. He had become progressively more paranoid and was constantly terrified of "beams and rays" causing damage to his body and of strangers poisoning him. The patient began to wear six layers of clothing at all times to deflect the "rays," kept the windows of his tiny basement-level apartment sealed, and ate and drank little. This behavior continued during an August week of temperatures in the high 90s, at the end of which the patient was admitted. Thus, it appeared that the patient's psy-

chosis was ultimately responsible for the heat stroke through the intermediacy of paranoid delusions.

Brooklyn, N.Y.

Countering Diazepam Abuse

SIR: Diazepam has been the most frequently prescribed drug in the United States since the early 1970s (1). It is also a unique drug—overcompliance rather than noncompliance is often observed with diazepam. Indeed, about 7% of all psychiatric admissions have a history of such sedative abuse (2).

The pharmacy department at the Buffalo General Hospital Community Mental Health Center surveyed all new diazepam prescriptions written in the emergency room during one year. The most disturbing finding was that a number of patients who were wise to the shift rotations of different psychiatrists had managed to receive several prescriptions for diazepam within a three- to four-day period. In two cases, individuals had gotten enough diazepam to last three months. The pharmacy department, wishing to combat this diazepam abuse, compiled a list of diazepam "addicts" (regular seekers of new diazepam prescriptions) and posted it in the emergency room for psychiatrists to note before prescribing diazepam to anyone. Furthermore, a procedure was developed whereby patients who received diazepam prescriptions were given only a seven-day supply, with no refills authorized.

The pharmacy department then monitored all diazepam prescriptions written during the next year. Although these measures did not completely prevent suspected diazepam abusers from trying to obtain a quick, easy diazepam order, 28% fewer prescriptions were written compared with the previous year. Many addicts were finally confronted and made to realize that diazepam was not the panacea for all their problems. Some 24 of the 31 major abusers almost doubled the number of their appointments with assigned counselors. This gave them more opportunity to ventilate anxiety and everyday pressures than the drug could provide.

We believe that stricter control over diazepam prescription practices may help decrease dependency rates and encourage patients to make more use of their assigned counselors in learning to live with anxiety; it is addiction to anxiety that can lead to addiction to diazepam.

The Group Alternative in Private Practice

SIR: The Topical Papers on the future of mental health care delivery systems (November 1978 issue) are timely and deal with issues that should receive constant and continued attention.

However, in "Private Practice of Psychiatry: Future Roles," Zigmond M. Lebensohn, M.D., missed an important trend in private practice which offers some of the advantages of clinic practice without the red tape, the costs, or the mixed quality of services in a large bureaucratic system.

I refer to small, multidisciplinary, private group practice, which has increased rapidly in the past three years in Massachusetts. Groups run by psychiatrists (or psychologists), usually staffed by senior social workers and psychologists, supply long-term, short-term, group, and other modalities of services. They operate at the time of day they are needed, at a cost far below that possible in a community mental health center. The groups offer psychiatrists the opportunity to expand the use of their services while partaking of the skills of others. They also do away with the isolation of solo practice. I take issue with Dr. Lebensohn's statement on the futility of cost comparison. I believe specific attention should be paid to costs since this frequently determines where services are purchased and which services receive government support. Community mental health centers and community clinics are usually not neighborhood clinics, but serve a very broad catchment area. Statistics on the cost of these services are frequently suspect because they include only the clinic costs and not the cost of the state administrative hierarchy or the pension system, all of which eventually comes out of the taxpayers' pocket. The fact that these clinics do not pay taxes, which further increases their cost per unit of service to the community (compared with a private group which does pay) is also overlooked.

As a former general practitioner and a current community psychiatric practitioner, I am distressed over mental health facilities which look like community or neighborhood centers on planning maps or charts but are actually far removed from most of the recipients of their services. Those planning such mental health facilities ignore the existence of different types of neighborhoods in any small community, let alone in a catchment area.

Family practice is returning in medicine; family and community psychiatry should also be encouraged.

JOHN C. CONIARIS, M.D.
Framingham, Mass.

Dr. Lebensohn Replies

SIR: Dr. Coniaris has called our attention to a form of group practice that can provide good psychiatric care without red tape or excessive costs. The points he made are important and well taken. I regret that shortage of space prevented me from developing them more fully.

In APA Task Force Report Number 6 (1) there is considerable discussion of multidisciplinary private group practice (pp. 9–10). The quality of care in such groups is usually excellent and can be delivered at a cost much lower than that of most community mental health centers. Unfortunately, the distribution of these groups is still spotty. Their growth depends on individual initiative and should be encouraged.

When comparing costs, I found it necessary to rely on published data. The studies by Sharfstein and associates (2)

of 53 CMCHs indicated that the cost of one hour's psychotherapy by a psychiatrist in a community mental health center "could be approximated at $45." However, some of the centers surveyed estimated $70 per hour. I would agree with Dr. Coniaris that if one considered all the hidden expenses, a treatment hour in a community mental health center might cost nearly $100. Dr. Coniaris stressed the importance of including the cost of the state administrators and retirement system which "comes out of the taxpayer's pocket." The fact that these clinics do not pay taxes is also significant.

I agree that community clinics often serve rather broad catchment areas and are not really neighborhood clinics. This point deserves repeated emphasis. I have written about this in greater detail in "Pilgrim's Progress: Or the Tortuous Road to Mental Health" (3).

Amantadine and α-Methyldopa: Effects and Interactions

SIR: In "Amantadine-Induced Psychosis in a Geriatric Patient with Renal Disease" (January 1979 issue) Richard Borison, M.D., Ph.D., made the point that amantadine "should be used only after careful clinical evaluation of renal function, particularly in the case of the geriatric patient." The case history well illustrates this point. However, it might also as well be used to illustrate some perhaps more fundamental principles of drug treatment that probably would have prevented the patient's ensuing complications.

1. One should avoid polypharmacy if possible. Parkinson's disease was only suspected, apparently on the basis only of a "bilateral resting and intention tremor of the hands." The patient was, however, described as caring adequately for herself and actively engaged socially in her church organization. Patients with early parkinsonism may have clinical features that warrant medical consultation, but if these symptoms cause no more than mild embarrassment or minimal inconvenience it may be best not to treat them because the chances of adverse effects with any of the available drug treatments probably exceed any likely benefits (1). Adverse effects would, of course, be of even more concern in a patient already taking multiple medications for multiple chronic medical problems. In addition, the patient's standing medication included α-methyldopa, 250 mg q.i.d., which in itself may cause parkinsonism as a side effect (2). Thus if the patient's symptoms were severe enough to warrant treatment, one might first consider altering the antihypertensive medication before adding a new drug.

2. If multiple drugs are prescribed, one should be aware of their possible interactions. As noted, the patient was taking α-methyldopa, which has profound effects, not to mention its main therapeutic mechanism of action on CNS dopaminergic systems, the same neurotransmitter systems that amantadine presumably affects in its therapeutic usefulness for parkinsonism. α-Methyldopa has been implicated, usually in association with other drugs that also affect central dopaminergic systems (e.g., haloperidol), in the causation of paranoid hallucinatory states (3). Dr. Borison correctly referred to Postma and Tilburg's 13 collected cases of apparent amantadine-induced psychosis in patients who were elderly, some in renal failure. However, 11 of their 13 patients were also taking other medications known to affect CNS neurotransmitter systems (one was taking methyldopa, 250 mg three times a day), which makes it pertinent to consider drug interaction in the etiology of these patients' psychoses (4).

3. In prescribing a particular drug, one should be aware of its pharmacokinetics and the clinical guidelines on dosage, which should be broken only with good reason. This patient was started on amantadine, 100 mg t.i.d. It is unusual for therapeutic benefits of amantadine to outweigh side effects at dosages above 200 mg. In the *Physicians' Desk Reference* the recommended starting dose of amantadine is 100 mg b.i.d., or in patients with serious medical problems, 100 mg q.d. Patients taking amantadine can develop congestive heart failure, which this patient already suffered from. In addition, as Dr. Borison stated, amantadine is in great part not metabolized but rather excreted in the kidney, and dosage therefore should be carefully introduced in someone who is known to have chronic renal failure. However, methyldopa is similarly excreted rather than metabolized, and the interaction of these drugs may have been therefore intensified. Indeed, bradycardia is a reported side effect of methyldopa, and one wonders about its relationship to the patient's chief complaint of bradycardia.

Dr. Borison Replies

SIR: I agree wholeheartedly that the use of multiple drugs presents the possibility of potentially toxic drug interactions, particularly in a patient with multisystem disease. In response to the first and third points discussed by Dr. Cohen, I agree that the patient's apparent early parkinsonism was treated too aggressively. In fact, on closer neurologic examination, the patient's muscle tone was not affected, there was no bradykinesia, nor was there a compromise of postural reflexes. When further history was obtained, the patient revealed that her father and paternal grandfather both had tremors of the upper extremities. With this information, the

final diagnosis arrived at was benign familial tremor, rather than Parkinson's disease.

I must take issue with Dr. Cohen's strong emphasis on the interaction of α-methyldopa and amantadine as being potentially responsible for the patient's psychosis. Both drugs do affect dopamine systems; however, they do so in a differential fashion. Methyldopa is metabolized to the partial agonist methyldopamine, which depletes brain dopamine by serving as a false neurotransmitter, whereas amantadine has been suggested to either release or block the reuptake of presynaptic dopamine. Thus, if amantadine blocks reuptake, it would attenuate the actions of methyldopa. Alternatively, if amantadine releases stored presynaptic amines, it would release methyldopamine, which is a partial dopamine receptor agonist. Therefore, in either case, the interaction of amantadine and methyldopa would not be expected to result in a psychotic state. I also take issue with the comparison of the methyldopa-haloperidol interaction with a methyldopa-amantadine interaction. Haloperidol is a blocker of postsynaptic dopamine receptors, a mechanism of action clearly different than that of amantadine. Moreover, the addition of methyldopa to haloperidol therapy may in fact enhance its antipsychotic actions (1).

Psychoanalytic Theory and the Dilemma of Precision

SIR: Anthony L. LaBruzza, M.D., in "The Activation-Synthesis Hypothesis of Dreams: A Theoretical Note," his criticism of Drs. Hobson and McCarley (December 1978 issue), may not have realized how his reliance on the concept of confusion of independent logical orders weakens his argument. The more psychoanalytic theory defends itself by refusing even the modest, "less exact" isomorphism used by Drs. McCarley and Hobson, the more it resembles an enterprise like scholastic philosophy. While a medieval theologian transported into a modern physics department might appear to ward off critics by the "no isomorphism" argument, that very security would erode his claims to describe reality as a candid look at the history of ideas demonstrates. The analogy to scholasticism suggests that the precision aspired to by psychoanalytic theory opens it to attack from other logical orders. Hard science leaves more modest psychologies and vaguer theologies in peace, if only out of politeness. A theory's explanatory power may not be subject to refutation for reasons summed up by Dr. LaBruzza and Gerald W. Vogel, M.D., in "An Alternative View of the Neurobiology of Dreaming," but its own inability to meet rough and ready challenges from other, more rigorously testable logical orders may weaken it fatally. An irrefutable place is not necessarily a safe place to be.

I thought Dr. Vogel's neurophysiologic comments a much more formidable criticism of McCarley and Hobson, although not supportive of analytic theory.

HUGH C. MURRAY, M.D.
Seattle, Washington

Dr. LaBruzza Replies

SIR: If Dr. Murray feels that, like a modern Thomas Aquinas, I have come to the defense of psychoanalytic dogma with "irrefutable" logic, I am flattered by the comparison, but he has misunderstood me.

I simply wanted to point out a major logical flaw in Hobson and McCarley's reasoning and thus challenge their conclusion that "the primary motive for the dream language and dream process cannot be disguise if the prime force of dreams is not an instinct or repressed 'wish' in need of disguise" (p. 1219). The terms "motive" and "force" belong to different logical orders and are not freely translatable to one another.

There is no argument that the firing of cells in the pons or anywhere in the nervous system is motivationally neutral. Are we to conclude, however, that because the neurobiological substrate for human behavior is the motivationally neutral firing of neurons, human behavior cannot be motivated? This ineluctable conclusion of Hobson and McCarley's line of reasoning flies in the face of clinical and human experience.

Hobson and McCarley appeal to a mind-body isomorphism that has not yet been scientifically demonstrated. At this point in the history of science such an isomorphism is a matter of faith. I do believe that an isomorphism or a superordinate framework for discussing meaning and physiology simultaneously will be discovered. I am not taking a stand for psychoanalysis and against empirical science. Both are necessary and valuable; neither should be accepted uncritically.

It would be unfortunate if our profession became polarized into warring factions, with psychoanalysis at one extreme and hard science at the other. Thoughtful scientists and theorists are sensitive to issues of multiple levels of explanation and their distinct, nontranslatable languages and methodologies (1–3). I highly recommend Kety's article (1) in this regard.

To cite a familiar proverb, we are all blind men touching upon various parts of the elephant. Together we might catch a glimpse of the whole.

BOOK REVIEWS

Legal and Ethical Issues in Human Research and Treatment: Psychopharmacologic Considerations, *edited by Donald M. Gallant, M.D., and Robert Force, LL.M. New York, N.Y., SP Medical & Scientific Books (Spectrum Publications) (Halsted Press, John Wiley & Sons, distributor), 1978, 180 pp., $15.00.*

This volume is the result of a symposium sponsored by the American College of Neuropsychopharmacology. The list of contributors is distinguished, representing the fields of law, ethics, philosophy, and psychiatric research.

The book is divided into six chapters with a preface. The first chapter is a presentation of the American College of Neuropsychopharmacology's principles of ethical conduct for research on human subjects. This document has been extensively reviewed and serves as a useful guideline for all researchers. The next two chapters review issues of current litigation and law as they affect psychopharmacological research and treatment. Chapters four and five review the ethical issues of psychopharmacological research and treatment, respectively. The last chapter, developed by the two editors, details some specific recommendations for public policy and individual action in this area.

Each chapter is followed by comments from a variety of experts in the field. Judicious editing has made these discourses lively and relevant. The comments are directly related to the position papers they follow and present opposing or clarifying points of view.

The area of human rights and research has been widely reviewed and debated since the end of World War II. The Nuremberg trials served to direct attention to the potential for abuse of individual rights and human dignity in the name of scientific research. An outgrowth of those trials was the Nuremberg Code, which continues to set forth fundamental principles that should govern all human research. The last decade has seen an increased awareness of individual rights coupled with a distrust of intellectual and scientific pursuits. Such concerns, added to the history of Nuremberg, have stimulated a debate about human biomedical research. Added to these general concerns have been the awareness of the potential of behavior control and the misuse of psychiatry for political or social purposes. One wonders whether this latter controversy would have developed if there had not been solid basic scientific work with significant advances in clinical care. How else can one understand the demand for access to treatment concurrent with a move to curtail research?

Most of the experts in this volume develop positions that seem to polarize the interest of "the scientist" and "the public." It is interesting that the public position is detailed by "experts" who speak in behalf of a presumed public stance and/or ethical, moral position. One is left with the feeling that they have been sanctioned to act on the behalf of others; of course, this is not the case. In that sense, all of the public sector protagonists are acting *in loco parentis,* a curious position, it seems to me, for those who claim to speak for human rights, particularly the right of self-determination and individual dignity. This is a side issue because "the public" must always have a voice, even if it is a self-appointed one.

To my mind, the issue has been unfortunately limited, centering on such various concrete issues as informed consent, selection of subjects, and right to treatment. I think it is probably natural that the issues arise around specific issues; however, such narrowness risks missing the broader problems that lie behind these specifics. The conflicts of the values, priorities, and philosophical positions that are the basis for the controversy remain obscure. In our pluralistic society, particularly as social changes occur, it would be surprising if we did not have such arguments. It is unlikely that in the foreseeable future conflicts in values will be easily resolved. Furthermore, the debate is likely to remain narrow and concrete.

As for the book itself, I found it an excellent volume. There are good reviews of the current legal status of research and aspects of psychiatric care. Issues such as the right to treatment, informed consent, and malpractice applications to research are adequately covered. The legal opinions and statutes cited are interpreted by people of opposing views, thus leaving one a sense of the liveliness and continued evolution of this field. The liveliness of the field underlines the fact that any publication must be a bit out of date even when just published.

I would have found it a bit more satisfying to have the ethical issues presented before the review of the legal material so that the underlying issues could be identified and thus form the basis for the practical legal debate. It was somewhat disappointing that the ethical and philosophical sections do not include as broad a review as might be desirable of the basic debates and various historical positions concerning human dignity, individual and public rights, and related matters. For those not thoroughly familiar with the relevant aspects of philosophy, this would have been an extremely useful addition to the book that would have helped focus the various arguments. There are places in the volume where these matters are addressed, but usually in a narrow or fragmentary way. Occasionally, the positions are concretized into adversarial arguments that are narrow and legalistic and distort the philosophical assumptions that underlie them.

In spite of these reservations, I am happy to recommend the book. I believe it is the best volume I have seen on its subject. It balances the various positions in these controversial areas. I recommend it as must reading to all researchers who are interested in clinical as well as basic science problems. In addition, lawyers and the judiciary interested in psychiatric research and treatment will find the book interesting. Those involved in public policy and administration of hospitals and medical schools will also find something of use, as well as specialists in philosophy, bioethics, and history of science. These specialists may look to additional readings and wish for more detail in their own areas; nonetheless, the book is an outstanding source of current review.

JOE P. TUPIN, M.D.
Sacramento, Calif.

Phencyclidine (PCP) Abuse: An Appraisal. NIDA Research Monograph 21, *edited by Robert C. Petersen, Ph.D., and Richard C. Stillman, M.D. Rockville, Md., National Institute on Drug Abuse, 1978, 313 pp., no price listed (paper).*

Useful books are timeless or timely. This one is timely. The major clinical event of the 1970s has been phencyclidine abuse. It was virtually a nonexistent clinical entity before 1970, but now it constitutes a prominent hospital admission category in some cities. One of eight young adults has tried phencyclidine. More than the effects of abuse of any other substance, the organic brain syndrome associated with phencyclidine abuse seems to mimic schizophrenia, and phencyclidine use appears to produce an extreme exacerbation of the signs and symptoms of schizophrenic patients. However, phencyclidine has gone largely unnoticed by psychiatry.

This book evolved from a conference held by the National Institute on Drug Abuse in February 1978. So we have the rarity of a book published the same year as the conference on which it is based. The price for the speed is some redundancy, some errors, and no index. The redundancies are bearable for a fresh field; the errors are not lethal but consist of things like labeling chapter 17 as chapter 12. The lack of an index, however, is quite disappointing because this is the only available reference book.

Knowledge about phencyclidine (PCP, Sernyl, Sernylan, angel dust, elephant tranquilizer, and a dozen other street names) has developed only over the past two decades. It produces a stimulant response in mice, calms guinea pigs, and anesthetizes many other animals. Rhesus monkeys like it so much it is used as a reinforcing agent (unlike hallucinogens). For man, the possible effects include all of the above plus many others. It is lethal in high doses, and in lower doses it can produce a variety of behaviors that remind one of schizophrenia. One contributor to this book, Paul Luisada, states, only partly in jest, "The widespread use of phencyclidine in our catchment area might even be viewed as a crude 'screening test' for 'schizophrenicity.' " How the drug produces any of these phenomena is a mystery.

Also a mystery is why monkeys and man should willingly take the drug. It has always had a poor reputation on the street, and some negative effects are felt virtually every time it is taken. Along with the negative effects, two-thirds of the time there is a change in feelings that is regarded as positive enough to attract, even to habituate. Habituation, it is hypothesized, occurs with those who do not like their "normal" feelings or with those who enjoy a reduction in their own basic drives to the point where they can feel quite content with being nothing and having nothing. These hypotheses have considerable explanatory power, but the test for clinicians is the hypotheses' usefulness in treating patients, and day-to-day management does not yet include such concepts.

Treatment for phencyclidine abuse derives more directly from basic research than is usual with many mental illnesses. Because phencyclidine excretion has been found to be markedly increased in acidified urine, therapy consists of acidification of the urine. Because basic experiments found increased disturbances with increased stimuli, therapy consists of stimuli reduction. Laboratory experiments also suggest the use of haloperidol, not chlorpromazine, but this is not universally accepted.

What about prevention? Giving the drug bad publicity will not work alone—it has had a bad press for over a decade. Increasing penalties for illegal manufacturing and distribution will only put it out of the price range of a few. With today's limited prevention skills, phencyclidine use will probably run a course like cocaine use, with periods of popularity. Psychiatry will have to respond effectively to many citizens whose phencyclidine use produces a brain syndrome and to the few who seek treatment for their habituation. For the professional, this book provides all we know about phencyclidine.

ROGER PEELE, M.D.
Washington, D.C.

The Woman Patient: Medical and Psychological Interfaces, Vol. 1: Sexual and Reproductive Aspects of Women's Health, *edited by Malkah T. Notman, M.D., and Carol C. Nadelson, M.D. New York, N.Y., Plenum Press, 1978, 358 pp., $19.50.*

This 25-chapter book is generally well written and carefully thought out. It is understandable to interested people who are not in one of the health professions and presents in one volume contemporary feminist views on all aspects of women's sexual functioning. *The Woman Patient* can appropriately be used as a reference for both women and men who want to know more about what obstetricians, gynecologists, and psychiatrists are doing with and for their female patients. The information is sound and, in most instances, carefully documented. The references and the glossary should prove highly useful to patients for years to come.

Chapters that proved of special interest to me were "The COPE Story: A Service to Pregnant and Postpartum Women" by Turner and Izzi, the review of the history of contraception in the United States by Peter Reich, and Kahan and Gachill's chapter on "The Difficult Patient: Observations on the Staff-Patient Interaction."

COPE, which stands for Coping with the Overall Pregnancy/Parenting Experience, is a self-help group program started by Turner in 1972. It now has 20 chapters in the metropolitan Boston area. Turner and Izzi describe COPE groups as "supportive and focused on problem solving" with the immediate goal of tension reduction. As described in the chapter, COPE offers a prototype that, if it becomes more widespread, could prove invaluable to many women during and after their pregnancies.

Both men and women psychiatrists can profit from familiarizing themselves with the views so cogently expressed in this book. Few physicians would be hesitant to recommend the book to patients. By reading this book, all health-care professionals who deal with women would have a fuller understanding of these patients and their many worries. We can all look forward to the future volumes of this promising series.

NANCY A. DURANT, M.D.
Plainfield, N.J.

The Mind in Sleep: Psychology and Psychophysiology, *edited by Arthur M. Arkin, John S. Antrobus, and Steven J. Ellman. New York, N.Y., Lawrence Erlbaum Associates (Halsted Press, John Wiley & Sons, distributor), 1978, 624 pp., $29.95.*

This book is a comprehensive review of EEG studies of the psychology and psychophysiology of sleep through 1975. It contains no review of neurophysiological aspects of the sleep cycle but is otherwise a worthy successor to Kleit-

man's encyclopedic work (1), which summarized the initial phase of modern sleep research.

Individual chapters effectively discuss various topics that have generated much research and controversy, such as the question of non-REM dreaming. (The distinction between content elicited on awakening from REM and non-REM sleep is less clear than originally believed, although REM content is still considered to be more dreamlike.) Other chapters discuss mentation associated with sleep onset, which can also be dreamlike; studies of dream recall (factors besides repression seem most important in normal people); the connection between tonic state, phasic events such as eye movements, and sleep mentation (not impressive); the effects of various external stimuli and drugs on sleep experience; and the effects of deprivation of REM sleep, which are often unclear and apparently contradictory. Another long chapter reviews such material of psychiatric interest as normative dream content, relation of dreams to psychopathology, psychophysiological parallelism, and dream meaning. I missed only a chapter on the psychological effects of total sleep deprivation, which would have been relevant to recent contentions that sleep is an archaic instinct serving no necessary function (2).

With an approach like that of the *Psychological Bulletin*, the authors have made a major contribution by reducing a huge mass of data to an accessible and relatively digestible form. Similarly, they present meticulous consideration of methodological issues. These critiques run the gamut from incisive clarification of ambiguous procedures, which will be essential guides for future research, to irrelevant carping.

The principal limitations of the book are in the areas of conceptual background and integration of the material. Much of the conceptual background, such as psychoanalytic theory, structuralism, psycholinguistics, cognitive psychology, and neuropsychology, has recently been well reviewed by Foulkes (3). His volume would serve as a companion to the present volume. The issue of integration reflects an enduring problem in sleep research. Maintenance of the interdisciplinary perspective that spawned the field has become increasingly difficult as workers have become mired down in parochial matters. Integrative attempts are made in the final two chapters. Although I agree with most of the authors' conclusions, the ideas presented in these chapters are separated by a significant gulf from the data of the previous chapters and also leave out a lot.

In summary, this work is a good presentation of the state of the art in sleep psychology.

CHESTER A. PEARLMAN, M.D.
Boston, Mass.

Psychosomatic Disorders in Childhood, *by Melitta Sperling, M.D.; edited by Otto E. Sperling, M.D. New York, N.Y., Jason Aronson, 1978, 406 pp., $20.00.*

A volume that is given the all-inclusive title *Psychosomatic Disorders in Childhood* and is written by a highly respected psychoanalyst, pediatrician, and teacher promises much, and this is unfortunate. In some respects the reader will not be disappointed. Melitta Sperling spent a lifetime working with (and curing) children suffering from psychosomatic problems. This posthumous book gives eloquent testimony to the clinical sensitivity, the masterful technique, and the patient perseverance of a superb analyst and therapist. Virtually every chapter contains a treasure of clinical detail, thought-provoking psychodynamic hypotheses, and treatment strategies that will be read with much profit not only by those who work with disturbed children but by all therapists who grapple with the problems of regressed patients with infantile personality organization.

The reader who is led by the title to expect a comprehensive examination of the current state of psychosomatic disorders in childhood, however, will likely be frustrated. Unlike many recent writers on psychosomatic disorders who affectionately but firmly place classical psychoanalytic insights in the perspective afforded by experimental and clinical studies of the past two decades (e.g., Herbert Weiner [1]), Sperling largely ignores or disregards these studies. Of some 380 references, only 11, including 3 references to her own work, are from the present decade. There is a charming but clearly anachronistic 1950s quality throughout, especially with respect to the author's staunch assertion of a primary psychogenetic etiology for all the psychosomatic disorders and also for epilepsy. Although Sperling recognizes that "some of my readers who are used to thinking of epilepsy as an organic disease . . . might take exception to my attributing meaning to the epileptic amnesia," she regards the epileptic attack as protecting the patient from acting out unacceptable criminal, perverted, aggressive, or sexual impulses.

The book consists of 25 chapters divided into 9 sections: an introductory section of 5 chapters devoted to theoretical and technical considerations and 8 clinical sections. These deal not only with classical psychosomatic conditions (ulcerative colitis, bronchial asthma, migraine, dermatoses) but also anorexia nervosa, tic disorders, and epilepsy. Otto Sperling, the late author's husband and a well-known psychoanalytic contributor, has edited the book and contributed an introduction, the opening chapter on "The Concept of Psychosomatic Disease," and two case studies on dermatitis and angioneurotic edema. Like his wife's clinical studies, these are interesting and instructive.

This book is well written and because of the fascinating clinical material it makes for pleasant and at times even stimulating reading. Seen in historical context, it is a valuable summary of the work of a psychoanalytic pioneer in the field of psychosomatic disease in children. Sperling recognized early the need to treat parents as well as the identified patient, the need to reduce and when possible to eliminate dependence on medication, the need to explore memories and fantasies from the earliest years in the lives of sick children, and the need to reduce the splitting and fragmentation that results from the "team approach" to these children. However, students of the mechanisms underlying the psychosomatic disorders will need to go beyond this book for a comprehensive and up-to-date understanding.

FREDERICK H. LOWY, M.D.
Toronto, Ont., Canada

Medicine and the Reign of Technology, *by Stanley Joel Reiser. New York, N.Y., Cambridge University Press, 1978, 307 pp., $14.95.*

Medicine increasingly relies on technological progress to achieve better diagnostic refinement and, consequently, therapeutic results. Many of the technical tools, such as the thermometer, the sphygmomanometer, and X rays, have become such regular routines that it seems as if they have always been with us. This is not the case, however. The acceptance by physicians of these and other important medical tools was at times unpredictable and was often related to progress achieved in the hard sciences like physics and chemistry. Conversely, the use of these medical tools resulted in substantial changes in medical practices and ultimately in better public health. These are two main points of Reiser's book. For each of the new tools, long controversies, often marked by bitterness and bias, ensued. In the end, clinical judgment and anatomopathological observation led to their daily use. This applies to the stethoscope, the ophthalmoscope, the laryngoscope, photography, X rays, the microscope, the sphygmomanometer, the electrocardiograph, the thermometer, and the various tests of urine, blood, gastric juice, and other fluids of the body—all developed some time during the past century.

The level of sophistication necessary to master the techniques related to these new tools contributed to the trend toward specialization by the medical profession and the public's increasing acceptance of the hospital and of private group practice. In retrospect, the advantage provided by refined technology in the hands of competent specialists was somewhat overshadowed by the loss of the old-fashioned family physician, a father figure who attended to the emotional as well as the physical needs of his patients and their families.

As Reiser puts it, in the first two decades of our century psychoanalysis focused on the importance of the patient's history; "conscious psychotherapy" was developed as an alternative means of evaluating and relieving emotional problems. However, he acknowledges that before World War II American physicians generally did not spend too much time exploring their patients' social and emotional experiences, and psychoanalysis also raised opposition from patients.

In spite of the shortcomings related to different evaluations of tests by various technicians, advances in telecommunication and in automation led to the introduction of highly specialized methodology, notably the cytoanalyzer and the computer in medicine. Regardless of the issue of how far the computer will go in replacing the specialist, the author concludes that "the healing of illness requires more than healing parts of the body; it also requires intensive efforts to communicate with patients." Further, he says, "The problems of illness hatched from beliefs, illusions, values, and other facets of cultural and mental life . . . are as forceful and significant as the biological problems of illness approached through technology and scientific learning."

This interesting and easily read volume by a clinician and medical historian, founder and director of the History of Medicine Program at Harvard Medical School, is directed at a wide audience. As such, it is largely expository and does not delve into a deeper analysis of sociocultural aspects related to technological developments (for instance, the so-called biophysical movement of the 1840s in German universities, which led to the level of excellence of their medical schools, and the interplay of physiological and political concepts by many scientists, beginning with Virchow).

Although it is not directed at psychiatrists, I think this volume may also be relevant for psychiatry, at least on two counts: on the one hand, technique appears to develop to the point of reaching a counterproductive level; on the other hand, the historical development of modern medicine is characterized by an increasing ambivalence between machine and humanism. These two issues are crucial to today's psychiatry.

GEORGE MORA, M.D.
Poughkeepsie, N.Y.

Down's Syndrome and the Family: The Early Years, *by Ann Gath. London, England, Academic Press, 1978, 128 pp., $13.25.*

In this short book Ann Gath reports her detailed medical and psychiatric observations on 30 families of infants with Down's syndrome and 30 well-matched families of normal infants. I know of no comparable controlled study involving a prospective follow-up of consecutively born infants with Down's syndrome and their families.

A total of 40 infants with Down's syndrome were born during the time of the study; 4 died in early infancy, 5 did not fulfill the criterion of living at home, and the family of 1 withdrew from the study. The physical and mental health of parents and siblings was assessed by interviews and questionnaires over a two-year period from the time the infant was diagnosed as having Down's syndrome. Teachers' rating scales were also used to assess siblings' behavior.

The most prominent finding in this study was that of greater marital disharmony in the families of infants with Down's syndrome than in the control families. Among the parents of the infants with Down's syndrome there were 2 separations and 1 divorce; a total of 9 of these couples were given a poor marital relationship rating. This was in contrast to no divorces or separations and no overall poor marital relationship rating among the control parents. In spite of the greater incidence of marital discord among parents of infants with Down's syndrome, the majority of the parents adapted well and did not have more medical or psychiatric problems than parents of the control infants. From the parents' marital histories, it appeared that marital disharmony and divorce or separation occurred mainly in those who had the poorest relationship before the birth of the handicapped infant. This logical and perhaps commonly observed phenomenon has not been well documented in previous studies. Gath's study also demonstrated that the degree of marital disharmony was not associated with the severity of developmental problems in the handicapped infant, since parents of infants with congenital heart disease, severe hypotonia, or severe feeding problems were not more likely to have marital disharmony.

It also appeared that couples with the most problems were the ones who were most socially isolated. They tended not to want public health nurse or social work contacts, although they did accept well the researcher's visits into their homes. In all, 12 couples had no contact at all with other parents of infants with Down's syndrome or with any professional agencies. Most of these parents did not seek support from the Society for Mentally Handicapped Children, and only 2 parents approached their local social service agency for help.

There were several less striking but equally important observations among the infants with Down's syndrome and their families. For example, one of the subjects was found to

have an inherited translocation, which created a great deal of anxiety and resentment in the carrier family; several members refused examination. Although this was the reaction of only 1 family, it is evident that greater understanding of the process of disclosure of such genetic findings is needed.

Another interesting finding was that subsequent reproduction was not affected by the birth of the abnormal child, since 9 parents of infants with Down's syndrome and 9 parents of control infants went on to have another child.

As suggested by previous retrospective studies, parents wanted to know their infant's diagnosis as soon as possible. Any delay in detection or disclosure of diagnosis appeared to create long-lasting anger and hostility toward the health professionals involved. The author also reports that the parents found medical clinics staffed with rotating doctors in pediatric training programs the least helpful, and, as would be expected, that specialized clinics for the care of handicapped children, where there was consistent contact with the same pediatrician, were the most helpful. Finally, although several mothers of infants with Down's syndrome were informed of hospital respite services, these were used in only one instance, and it appeared that even a short respite hospitalization suggested to the mother that the baby was being "put away."

The main shortcoming of this study is that two years is not long enough to measure the full effect of the handicapped child on the family. Especially in Down's syndrome, the infancy and preschool years may be the easiest period for the family. The author reviews previous studies of her own and others illustrating problems in the parents and siblings of older individuals with Down's syndrome (e.g., sisters of individuals with Down's syndrome have more antisocial adjustment). It was also disappointing that the author's study is strictly descriptive and does not attempt to measure the effect of any form of early family intervention. There is also an editorial problem caused by repeated referral to material from the author's previously reported survey of the siblings of individuals with Down's syndrome, which is not included in the text as an appendix.

In her final recommendations the author reviews the theory that parents may be most susceptible to intervention during the first year after the birth of a handicapped child (1) and suggests some form of early crisis intervention for parents of infants with Down's syndrome. Since marital disharmony was greatest in parents with the most problems before the birth of the handicapped child, intervention could be directed toward these higher-risk families. My associates and I have proposed a model for such intervention (2), but experience has shown that parents are not likely to participate in weekly counseling sessions without some evidence of direct benefit to the affected child. The author's finding that parents who did not want public health nurse or social work contacts were still accepting of the researcher's regular home visits suggests that future attempts at early family intervention may come about through the professional's presence in the home. This may be of particular benefit for parents who are most likely to be burdened by the care of a handicapped child.

In summary, the observations and recommendations put forth in this book are most timely and welcome and should benefit health professionals involved in the care of handicapped families.

A Social Interactional Theory of Emotions, *by Theodore D. Kemper. New York, N.Y., Wiley-Interscience (John Wiley & Sons), 1978, 434 pp., $19.95.*

In order to understand the interplay of emotions in social relationships, Kemper has ambitiously sought "a principle that can perform the same function as gravity in classical mechanics." He has chosen the "power-status" model of social interaction for this purpose. This book consists of an exposition of his theory based on an extensive review of the literature. Kemper has selected about 900 references on the physiology and psychology of emotion and the psychology and sociology of social relationships; no new data are presented. Topical chapters include a detailed structural formulation of emotions as these are affected by the power-status variables existing between two people, an analysis of the physiology of emotions in human relationships, a theory of schizophrenia and depression in power-status terms, and analyses of "punishment" and "love" from the standpoint of this theory.

Despite the diversity of academic fields and reports surveyed, the author presents his material in a lucid, flowing, and readable form. Simply as a review of the broad literature on emotions and the power-status model of social relationships, the work is valuable. At times, however, the author seems to be forcing all available observations into a single theory unable to contain them.

Psychiatrists will be disappointed with the author's treatment of depression and schizophrenia: his reinterpretation of clinical "facts" often fails to ring true and is largely a rehash (although using new terminology) of Freudian theory on the etiology of adult psychiatric disorders in child raising practices. The author's theory itself, with 1,701 "possible" emotions and 168 "likely" emotions, does not lend itself to ready clinical application, but it would definitely interest many psychological or physiological researchers studying emotion. Child and adolescent psychiatrists, as well as forensic and prison psychiatrists, should find the chapter on punishment and "distressful emotions" useful. Most psychiatrists, and especially those seeing couples, would gain from the two chapters on "love as a social relationship," with their cogent exposition of intimate relationships from the conceptual viewpoint of power and status.

Beyond the Double Bind: Communication and Family Systems, Theories, and Techniques with Schizophrenics, *edited by Milton M. Berger, M.D. New York, N.Y., Brunner/Mazel, 1978, 254 pp., $16.95.*

Twenty years after the presentation of the now famous paper "Toward a Theory of Schizophrenia" by Bateson and associates (1), a follow-up conference was held titled Beyond the Double Bind. (The reader will, I trust, be aware

of the concept of the double bind theory as it applies to the understanding of schizophrenia—if not, this book presents the original paper for review.) The aim of the conference was to explore the heuristic effects of the double bind theory as seen by leading family therapists, including all of the living authors of the original paper. In addition, such notable communications theorists or family therapists as Bowen, Scheflen, Wynne, and Whitaker present their current thinking about psychotherapy and the double bind concept as it applies to the treatment of severely disturbed individuals and families. The conference papers have been carefully edited for presentation in book form.

This is not a book for beginning family therapists. The authors do not develop their theories of psychotherapy with schizophrenic patients in a sequential manner. They assume that the reader has some background in communications theory and family systems therapy. The presentation of the original double bind paper at the beginning of the book is not intended to provide adequate background for the novice therapist but, rather, to pay respect to the concepts being explored and to serve as general background for the presentations. The book has considerable value, however, to the more experienced therapist who wishes to reevaluate his or her thinking on the treatment of severely disturbed individuals and families.

This book provides a rare opportunity to, as it were, sit alongside leaders in the field of family therapy and learn from their experience over the past 20 years in the treatment of schizophrenia.

Toward a Theory of Psychosomatic Disorders: Alexithymia, Pensée Opératoire, Psychosomatisches Phänomen, *edited by W. Bräutigam and M. von Rad. Basel, Switzerland, S. Karger, 1977, 388 pp., $53.50.*

In their incisive introduction describing papers given at the 11th European Conference on Psychosomatic Research, Bräutigam and von Rad outline the major themes considered in this volume. They point first to the two diverging attitudes toward psychosomatic research: one tends more to specify disease, the other to find a common denominator in different disorders. The latter approach, they say, was magnificently formulated by Jurgen Ruesch in 1948; he described the affective deficiency in communication, in fantasy, and in social behavior as belonging to an "infantile personality." It is against this background that the new terminology of alexithymia, pensée opératoire, and psychosomatic phenomena appear.

The editors also saw the meeting as embracing endeavors to differentiate psychosomatic patients from psychoneurotic patients. The definition of alexithymia by Sifneos and Nemiah puts a seal of significance on the observations of many others dating from the 1940s and 1950s. Their efforts to clarify and measure this concept put us in their debt. Concurrently the French workers Marty and de M'Uzan have developed a parallel concept called pensée opératoire. Both deal with the difficulty many patients, especially those with psychosomatic disorders, have in communicating feelings and expressing fantasy. Other European psychiatrists speak of psychosomatic phenomena in a similar way, but the three terms are by no means synonymous despite their appearance on the cover of this book. Furthermore, these terms often mean somewhat different things to different people. The more than 40 papers in this book show how widely the term "psychosomatic" varies from the classic "holy seven."

The book begins with 4 splendid papers on basic concepts. This is followed by a section titled Observations that begins with Sifneos and associates' studies of alexithymia in neurotic and psychosomatic patients. The other 17 papers add useful variations on the assessment of alexithymia in different conditions, including commissurotomy, ulcerative colitis, and pensée opératoire in obesity. Nemiah and associates add a new dimension with their study of oxygen consumption in response to affect-provoking thoughts. The causes of and mechanisms involved in alexithymia excited much discussion, but no consensus emerged.

The third section, titled Theories, begins with Nemiah on theoretical considerations followed by MacLean on the triune brain and the Heibergs on a study of twins. These are stunningly good contributions. The other 7 papers are useful and provide many significant elaborations, especially on the role of the family.

In the fourth section therapeutic approaches are elucidated. Bastiaans emphasizes the importance of the patient's feeling of safety denied by deficient coping strategies, particularly in the area of communication. Therapy in psychosomatic disorders should aim to restore a sense of safety, which may be encouraged by supportive and group therapy. There seems to be a consensus that formal psychoanalysis is contraindicated because dynamic insight therapy can be used only after the milder approaches, such as relaxation and group therapy, have decreased the patient's rigidity. The authors most referred to in this section are Winnicott for his sage explanations of early relationships and McDougall for her insightful explication of early developmental processes, of importance to an understanding of alexithymia and pensée opératoire in 1974. The authors might well have quoted one of McDougall's most pungent remarks: "Research into the meaning and treatment of psychosomatic illness is at the crossroads of various scientific disciplines." This is a succinct commentary applicable to the field and to this meeting.

The final 2 papers, in a section titled Varia, try to discuss the lives of Blaise Pascal and Pinocchio from a psychosomatic point of view. It is a pity that the conference did not finish with a more rigorous scientific approach because this is the main criticism of the whole book. Since there was considerable diversity of opinion as to what psychosomatic phenomena or disorders should be considered the proper area of interest, it is not surprising that considerable nebulousness reigns. Despite the fact that it was called a research conference, too many papers with no research orientation marred the program.

Aging: The Process and the People, *edited by Gene Usdin, M.D., and Charles K. Hofling, M.D. New York, N.Y., Brunner/Mazel, 1978, 239 pp., $15.00.*

This volume from the American College of Psychiatrists clearly presents current knowledge and theories of the aging.

process and elderly people. It should be useful as a basic text for students of any discipline concerned with gerontology or with services for aging citizens. In the introduction Gene Usdin points out that interest and understanding of normal and pathological aging is intriguing and challenging, should benefit older patients, and, from a selfish view, should smooth our own later years.

The "Overview on Aging" by Robert Butler provides demographic information and considers the role of finances, emotional and mental problems, and "professional neglect." He stresses the need for research, education, service, and attitudinal changes.

In "Social and Cultural Context of Aging" George Madox uses "differential gerontology" to accentuate the wide variation in functional capacity, socioeconomic status, and coping styles of older people of the same chronological age. He stresses the need for creativity in meeting needs in such areas as finances, health care, and transportation. He also questions society's values and attitudes.

Theories and current research on the "Biology of Aging and Its Role in Depression" are outlined by Morris Lipton and Charles Memeroff and emphasized by their conceptual figure of "a multivalent model of depression." Their tables on age-related changes in catecholamines and related enzymes, on indoleamines, monoamine oxidase, and cholinergic systems, and on amino acid transmitters provide an excellent basis for information on current thinking and should give direction to further research.

In "Psychophysiologic and Cognitive Studies in the Aged" Carl Eisdorfer describes the difficulties in studying and differentiating normal aging and a pathological process. He reviews the psychophysiologic studies that have shown significant findings and have been replicated, but in spite of the progress made in the past decade the need for research into accurate measures of normalcy and disease is obvious.

Ewald Busse's "Review and Critique of Aging Research" points to further areas of study, such as EEG, sleep, sex differences, and sexuality. He defines research and its subtypes, making a plea for continued basic research.

In "Death and Dying" Thomas Holmes describes the attitudes and expectations of societies and the interaction of these stimuli with the psychophysiologic mechanisms that result in the response of death.

Bennett Gurian and Marjorie Cantor deplore the neglect of the elderly consumer in "Mental Health and Community Support Systems for the Elderly." As one who has focused on geriatric services in a community mental health center for many years, I would argue with some of their statements. For example, I do not agree with Robert Weiss that the helper must be perceived as an ally by the distressed individual to give support. Confrontation of the dysfunctional older person is the role of those in a support system, even if the patient views the supporter as an enemy. Although I agree that services should be provided in a setting in which "there is interdisciplinary training and a wide range of services, such as a teaching hospital," an interested psychiatrist can be a one-man team in any setting.

"Aged Patients, Their Families, and Physicians" by Charles Gaitz sums up many of the areas in working with an older patient for consideration. Although there is overlap of material in many chapters, the attitudinal consensus and the individual viewpoint of each writer make this volume a valuable addition to the literature.

SHIRLEY M. COLTHART, M.D.
Rochester, N.Y.

Progress in Experimental Personality Research, Vol. 8, *edited by Brendan A. Maher. New York, N.Y., Academic Press, 1978, 340 pp., $23.00.*

Progress is a difficult thing to recognize in personality research. Findings accumulate and conceptualizations become more sophisticated, but the degree to which our knowledge is higher, better, or more advanced is uncertain. The six articles in this volume cover a variety of topics (empathy, violence, drug abuse, schizophrenia deficits, female criminality, socialization), but progress is not a recurring theme. Nonetheless, all the articles provide thorough and interesting overviews of complex subjects.

Schizophrenia researchers will find the Oltmanns' and Neale's discussion of deficit research very worthwhile and challenging. After reviewing the theories of Vygotsky, Goldstein, and Arieti and then critiquing data from object sorting, proverb, and other reasoning tests, the authors present a brief but compelling section on fundamental aspects of methodology in schizophrenia research. We are reminded, for example, that even schizophrenia research analyzed with t tests or analyses of variance is basically correlational and not experimental because the "critical variable—schizophrenic control—has not been manipulated nor have subjects been randomly assigned to either of these conditions." Matching schizophrenic and control groups, for instance, is a common aspect of the experimental paradigm, but the matching procedure itself can introduce severe artifacts because of "third" variable influences. Everything about schizophrenia continues to lure researchers from many fields; this article is worthy of their careful attention.

A lively review by Pihl and Spiers of research on the addictive personality concept will be discouraging to would-be researchers in this area. After a careful and illuminating consideration of previous work, the authors essentially are left with the generalization that the addicted individual is troubled. This area is ripe for creative research strategies. Perhaps as genetic and biological predispositions to drug addiction are researched more carefully the role of personality and social factors will become more clear.

Geen's paper on the effects of observing violence and Fesbach's paper on empathy in children are the best examples in the volume of the experimental approach to personality research. The Geen article summarizes findings in the field and provides an overview of how researchers study a phenomenon in the laboratory and in the real world. Fesbach's paper concentrates on reporting the results of a specific project and is therefore a bit more narrow in appeal, but it too illustrates the experimental approach. Violence and empathy are favorite topics for personality researchers, but progress in these areas is particularly difficult to judge because of the problems associated with generalizing laboratory findings to the real world.

Female criminality is the subject of Widom's paper; her review highlights many important problems. Typing offenders on the basis of personality characteristics rather than for the crimes committed appears to be one promising area for more research, as does exploring further the relationship between crime and psychopathology. Social deviance always has been of special interest to personality researchers, and the fundamental question of sex differences in this area deserves much more attention.

The last paper in the volume is an informative piece on socialization in the Soviet child by Barlett. Since it is not empirical it seems a bit out of place with the other papers and with the volume's title, but it provides a noteworthy example

of the interplay of cultural assumptions, social policy, and social science. If experimental personality research is ever to have impact on social policy, a controversial prospect, then more topics like this need exploration.

There *is* progress in personality research, but it is slow and undramatic. Its promise in most areas has yet to be realized, but the field is vital and the questions remain provocative.

RICHARD J. HAIER, PH.D.
Bethesda, Md.

Progess in Clinical Neurophysiology, Vol. 3: Language and Hemispheric Specialization in Man: Cerebral Event-Related Potentials, *edited by John E. Desmedt. Basel, Switzerland, S. Karger, 1977, 282 pp., $47.25.*

This volume contains 18 chapters presenting studies on the topics mentioned in the title. Two deal with theoretical issues, 4 with perception of language, 3 with speech production, and the remainder with hemispheric asymmetries in linguistic and nonlinguistic tasks. Too much material is presented to review in detail; I will therefore concentrate on highlights that seem to me potentially most fruitful.

The introductory chapters on the psychobiology of speech and language make ample reference not only to the neurological literature establishing a dominant role for the left hemisphere in linguistic function but also to the burgeoning recent linguistic and psycholinguistic writings that have enunciated a theoretical framework for the detailed description and explanation of linguistic structures and, to some extent, aspects of their use in talking and in comprehending speech. Unfortunately, aside from a passing comment by Donchin and associates, these considerations are not evident in the studies reported. No studies bear on event-related potentials related to any of the important linguistic structures now articulated within this framework, nor to any of the well-defined hypotheses available from psycholinguistics regarding the processing of sentences. In part this is due to perceived limitations of the event-related potential technique, which requires repeated stimuli and experimental paradigms not easily constructable with these independent variables. I suspect it is also partly due to experimental clinical neurophysiologists' relative lack of familiarity with this literature and the concern they have with other psychological factors, such as attention, which figures notably in the volume. Donchin and associates' comments that interesting event-related potential effects, particularly in the late components of potentials, may reflect such variables seem to me most cogent and a possible direction for further work.

What is reported with respect to language is a good deal of material on event-related potentials and spectra-analyses related to perception of lexical and categorical ambiguity of individual words, perception of Haskins-generated synthetic syllables (with similar but nonlanguage material used as controls), and perception of such semantic aspects of words as their place on the Osgood semantic differential. In speech production, the book presents important cautions dealing with respiratory and oro-facial-pharyngeal-lingual motor contamination of cerebral potentials. The effects on the event-related potentials are not robust in the perception work, and much of the production work seems like a retreat from earlier claims regarding lateralization of speech-specific potentials. Many analyses of the perceptual data are post hoc, and, as Molfese reports, different analyses can lead to radically different results. This is not to say that the reports are uninteresting; indeed, I think some of them are remarkable, such as Chapman and associates' discovery of an event-related potential effect of the semantic differential. As a whole they provide evidence that abstract information coded in the linguistic signal is measurable neurophysiologically over selected sites, primarily the left hemisphere. It is to be hoped that further investigation, perhaps along the lines I suggested at the outset, will provide more data regarding these effects.

The studies on hemispheric specialization use a variety of techniques: spectra-analysis (both for frequencies and amplitudes), event-related potential data derived from tasks thought to engage one hemisphere preferentially, and event-related potential effects of interfering or competing with a task engaging primarily one hemisphere. Molfese's paper traces the ontogeny of some of the event-related potentials to a select but well-defined stimulus set. Almost without exception, the investigators found what they expected: visuospatial tasks engage the right hemisphere and language tasks the left. Of some interest (and concern) to me is the fact that interpretation of the data as a reflection of hemispheric involvement is to some extent arbitrary. Thus, most investigators in the third section of the volume accept the view that desynchronization of the EEG and decrease in its amplitude indicates increased processing in an area. How does this square with claims (such as in Roemer and Teyler) that larger amplitude variation in event-related potentials reflects local processing?

The authors are sensitive to these issues. The papers by Desmedt and Robertson and by Donchin and associates begin to develop a taxonomy of potentials with respect to psychological variables. The key division of event-related potentials in their view is along temporal lines. Early potentials are considered stimulus-specific, perhaps reflecting lemniscal and other fast-pathway transmission, and are lateralized to the opposite hemisphere. Potentials in the 50–200-msec range reflect attentional processes and stimulus characteristics such as frequency and modality. Late potentials, like the P300 and possibly the CNV, reflect abstract stimulus variables, are modality-independent, and are the consequence of "complex" and "endogenous" psychological manipulation of stimuli. Clearly, such taxonomies are only preliminary and are to be extended to encompass more of the variation of potentials and EEG spectra than can now be done, with the goal of developing a theory of the relevant neurophysiology.

Many authors remark that modern analysis of EEG spectra and event-related potentials constitutes our first foothold in the area of the neurophysiology of cognitive processes in intact man. The field is in its infancy; much empirical work and theoretical formulation will precede the kind of analysis that we have of information encoding and flow for peripheral nerve and many nonhuman perceptual and motor systems. This volume gathers together valuable papers that are representative of results and thinking in the field.

DAVID CAPLAN, PH.D., M.D.
Amherst, Mass.

Aging and Behavior: A Comprehensive Integration of Research Findings, 2nd ed., *by Jack Botwinick. New York, N.Y., Springer Publishing Co., 1978, 398 pp., $16.50.*

The title of this book, which is the second edition of a 1973 publication, is somewhat misleading in that the word "ag-

ing" suggests a continuous process but the book deals almost exclusively with the aged. The concept of process (the vital process of aging) is referred to minimally. Furthermore, and as a corollary, connections between early life and its impact on aging and the aged are denied. The author's allusion to a longitudinal process is a negative one, and he appears to be biased in his intentional exclusion of psychodynamic concepts. He attempts to discredit what is referred to as "the orthodox psychoanalytic view" in his chapter on simple rigidity:

> Rigidity has been thought to be a global aspect of man. Many psychologists, until relatively recently at least, behaved as if they also had this view of rigidity. *This was typified most extremely, perhaps, by the orthodox psychoanalytic view.* If there is fixation at a particular stage of psychosexual development, that is, if childhood development is not complete, having stopped at a particular point in the process, the resulting adult will be stunted in effectiveness by an obsessive thought system and by an excessive rigidity of behavior. (italics mine) (p. 87)

A few sentences later he writes, "Even if we were to endorse the premise that young adults can be classified on a continuum of general rigidity, and *even if we were to accept the notion that rigid personality is the result of earlier life experiences . . .*" (italics mine). It is this particular point of view that I find disturbing because it ignores the research and clinical studies of Spitz, Mahler, Freud, Erikson, Harlow, and Fraiberg, to mention a few. It should further be noted that in a bibliography of 674 references, there is no mention of the *Journal of Geriatric Psychiatry*, a publication that for more than 12 years has advocated a longitudinal and dynamic view of the process of aging. Indeed, the author's approach to behavior appears to be more physiological, as indicated, for example, by his chapter eleven. Titled "Processing Sense Information," it contains the following subheadings, Sequential Integration: Stimulus Fusion, Stimulus Masking, and Stimulus Enhancement, Stimuli Reflecting Common Experience, Sustained Attention; Temporal Integration of Non Sequential Information: Spiral Aftereffect, Color Afterimage, Time to Perceive Complex Stimuli, Illusions; Spatial Integration: Part-Whole Relationships, Modification of Percepts; Anoxia, Another Model; and Compensatory Adjustments.

One might have hoped that Dr. Botwinick could have presented a more rounded view of aging and behavior. Although he may not hold to the concepts of dynamic theory, a complete discussion of aging and behavior should indicate that such concepts exist and are more often than not the basis for considerable exploration, research, and writing.

MARTIN A. BEREZIN, M.D.
Boston, Mass.

Violence and Responsibility: The Individual, the Family and Society, *edited by Robert L. Sadoff, M.D. New York, N.Y., SP Medical & Scientific Books (Spectrum Publications) (Halsted Press, John Wiley & Sons, distributor), 1978, 133 pp., $14.95.*

The increasing public concern about violence and its social ramifications served as the impetus for a symposium on the subject at Philadelphia's Friends Hospital in 1976. This volume is a collection of nine essays delivered at the symposium by various distinguished authors. They discuss violence in intrapsychic, neurological, legal, and social contexts.

In general, the individual authors are to be commended for their clarity of thinking and readable style. Nevertheless, the essays represent only brief outlines of the frustrations and dilemmas in so broad a topic, serving to raise consciousness through an emotional appeal to the audience.

Unfortunately, there is little new information or research contained here. Some recommendations are advanced as to possible approaches, but few actual data are provided as to the efficacy of these solutions. In summary, the book offers an introduction to the subject of violence, directed toward the neophyte. As such, it presents a provocative first step to understanding but falls short of making any major contribution.

THOMAS C. BOND, M.D.
Boston, Mass.

Progress in Behavior Modification, Vol. 6, *edited by Michel Hersen, Richard M. Eisler, and Peter M. Miller. New York, N.Y., Academic Press (Harcourt Brace Jovanovich), 1978, 248 pp., $18.50.*

The purpose of this series on behavior modification is to present timely issues, new directions, and future trends in the field. Each of the six volumes' reviews begins with a short outline that aids the reader in maintaining organization. Despite the large number of reviews in the six volumes, there is very little overlap in subject matter. The previous volumes reviewed in the *American Journal of Psychiatry* have received excellent ratings.

There are seven original review articles in volume 6. These articles are well referenced and cover their topics in depth. "Behavioral Treatments for Insomnia," "Behavioral Approaches to Stuttering," and "Assessment and Treatment of Enuresis and Encopresis in Children" provide some practical treatment approaches to difficult clinical problems. "Behavior Modification in Latin America," "The Social Identity of Behavior Modification," "New Directions in Behavior Modification with Children," and "The Therapist-Client Relationship in Behavior Therapy" offer little therapeutic technique but provide excellent historical and theoretical discourses.

I feel that the first three articles in volume 6 have some value for clinicians. Overall, however, this is more of a reference book for the psychiatrist particularly interested in behavior modification.

GEORGE W. MIDDLEKAUFF, M.D., PH.D.
Chillicothe, Ohio

Adults and Their Parents in Family Therapy: A New Direction in Treatment, *by Lee Headley. New York, N.Y., Plenum Press, 1977, 190 pp., $14.95.*

The purpose of this slender book is to describe the value of including in psychotherapy the parents of adult patients who are being seen for either individual or marital problems. The author delineates her views of types of patients for whom this inclusion is valuable, the necessary conditions for proceeding, the types of problems encountered, and the

benefits of the experience for both the adult patients and their parents. The book is easy to read and enlivened by many case examples that convey the way the author does her work. However, this book is not a significant addition to the literature on family or individual therapy.

The nature and importance of intergenerational ties have been well delineated by Ivan Boszormenyi-Nagy and Geraldine Spark in Invisible Loyalties (1), which is unfortunately too little read. Although Nagy and Spark described their work with adults and their parents, they did not focus on the characteristics of the psychotherapy with this combination, which was described in thoughtful detail by James Framo (2). In a closely related area, Murray Bowen (3) has demonstrated that patients in individual therapy can be helped to return home to visit their parents and to change the characteristic and unrewarding patterns of interaction between them and their parents in the direction of greater individuation and mutual satisfaction. This work and its importance are not discussed in the body of Headley's book, although the Framo and Bowen papers are mentioned in the introduction.

I believe the author's tendency to be clearly on the side of her patients can have unfortunate effects. Although she states that therapists should be even-handed, it is evident from her case material that in the therapist the patient has an ally—"a friendly facilitator, who will assist him/her in case there are any unsuccessful binds with the parent." When tensions rise, she is quick to end the interview, which is probably a good thing, but often painful feelings must be aired before they can be resolved. Too often one has the sense that Headley wants her adult patients and their parents to reach an agreement about how to handle some problem in a practical way before the issues dividing them have been adequately raised and their interactional nature clarified.

This book may be of some interest to adult patients who are contemplating having their parents participate in their therapy. For mental health professionals, it does not add to the literature in this area and is an insubstantial volume in both size and thought.

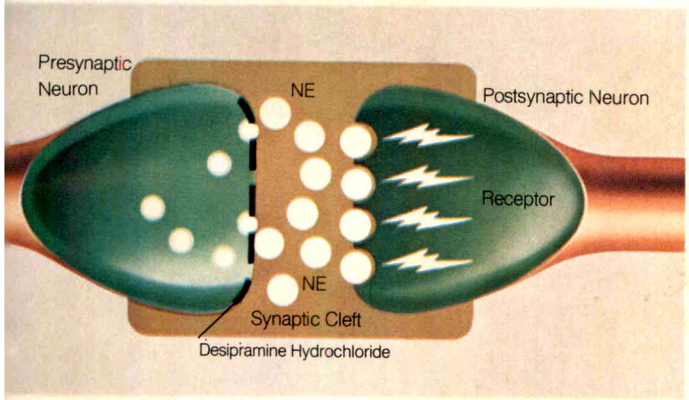
Bernstein, Basil G., M.D., Los Angeles, CA, was among those who successfully completed the Board examination given by the Committee on Certification in Child Psychiatry in New Orleans, LA, February 26–28, 1979. The other successful candidates were listed in the June 1978 issue of the *Journal*.

When your patient is clinically depressed...
"...everything I saw was negative."

...consider this potent blocker of norepinephrine re-uptake

The biogenic amine hypothesis states that depression may be associated with a deficiency of specific neurotransmitters—norepinephrine or serotonin—at brain receptor sites.[1] Tricyclics appear to block the re-uptake of specific neurotransmitters. Some tricyclics specifically block the re-uptake of serotonin; others block the re-uptake of norepinephrine.[2] Therefore, if your patient is unresponsive to treatment with one tricyclic, consider switching to a tricyclic which blocks the re-uptake of a different neurotransmitter.



(Electron micrograph of human synaptic cleft.)

Norpramin®
(desipramine hydrochloride tablets NF)

25, 50, 75, 100, 150 mg.

Potent blocker of norepinephrine re-uptake

According to current theory[1,3] some tricyclic antidepressants may fail in certain types of depression because they are not sufficiently potent blockers of norepinephrine re-uptake. Laboratory studies have shown that desipramine is the most potent inhibitor of norepinephrine re-uptake.[4] Norpramin may work in some patients when other tricyclic antidepressants do not.

Consider it now, consider it next.

Less anticholinergic activity

(See Warnings section.)

Studies in animals[5] and in normal human subjects[6,7] have shown that desipramine has significantly less anticholinergic activity than amitriptyline or doxepin. The single bond side chain is associated with lower anticholinergic activity than these other leading antidepressants. This may mean:

- less dry mouth
- less blurred vision
- less urinary retention

Helps patients remain calm but active

Norpramin does not usually inhibit normal activity although patients should be cautioned as to driving or operating machinery if drowsiness occurs.

In addition...

Begins to improve sleep patterns within one week in some patients[8]

- Norpramin helps relieve the sleep disturbances that often accompany depression.
- As the depression is relieved, the difficulty in falling asleep, restlessness, and early morning awakening diminish.

Merrell

Now 300 mg. dosage range broadens clinical flexibility

A maximum dosage of 300 mg. a day, as a single or divided dose, may now be prescribed for Norpramin. Since inadequate dosage is thought to be one of the major causes of treatment failure, the new therapeutic range should prove clinically helpful. Plasma desipramine measurement would constitute the optimal guide to dosage monitoring.

Norpramin®
(desipramine hydrochloride tablets NF)

AVAILABLE ONLY ON PRESCRIPTION

Brief Summary

MECHANISM OF ACTION: Available evidence suggests that many depressions have a biochemical basis in the form of a relative deficiency of neurotransmitters such as norepinephrine and serotonin. Norepinephrine deficiency may be associated with relatively low urinary 3-methoxy-4-hydroxyphenyl glycol (MHPG) levels, while serotonin deficiencies may be associated with low spinal fluid levels of 5-hydroxyindolacetic acid.

While the precise mechanism of action of the tricyclic antidepressants is unknown, a leading theory suggests that they restore normal levels of neurotransmitters by blocking the re-uptake of these substances from the synapse in the central nervous system.

Evidence indicates that the secondary amine tricyclic antidepressants, including Norpramin, may have greater activity in blocking the re-uptake of norepinephrine. Tertiary amine tricyclic antidepressants, such as amitriptyline, may have greater effect on serotonin re-uptake.

Norpramin (desipramine hydrochloride) is not a monoamine oxidase (MAO) inhibitor and does not act primarily as a central nervous system stimulant. It has been found in some studies to have a more rapid onset of action than imipramine. Earliest therapeutic effects may occasionally be seen in 2 to 5 days, but full treatment benefit usually requires 2 to 3 weeks to obtain.

INDICATIONS: Norpramin (desipramine hydrochloride) is indicated for relief of symptoms in various depressive syndromes, especially endogenous depression.

CONTRAINDICATIONS: Desipramine hydrochloride should not be given in conjunction with, or within 2 weeks of, treatment with an MAO inhibitor drug; hyperpyretic crises, severe convulsions, and death have occurred in patients taking MAO inhibitors and tricyclic antidepressants. When Norpramin (desipramine hydrochloride) is substituted for an MAO inhibitor, at least 2 weeks should elapse between treatments. Norpramin should then be started cautiously and should be increased gradually.

The drug is contraindicated in the acute recovery period following myocardial infarction. It should not be used in those who have shown prior hypersensitivity to the drug. Cross sensitivity between this and other dibenzazepines is a possibility.

WARNINGS: 1. Extreme caution should be used when this drug is given in the following situations: a. In patients with cardiovascular disease, because of the possibility of conduction defects, arrhythmias, tachycardias, strokes, and acute myocardial infarction. b. In patients with a history of urinary retention or glaucoma, because of the anticholinergic properties of the drug. c. In patients with thyroid disease or those taking thyroid medication, because of the possibility of cardiovascular toxicity, including arrhythmias. d. In patients with a history of seizure disorder, because this drug has been shown to lower the seizure threshold. **2.** This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. **3.** USE IN PREGNANCY: Safe use of desipramine hydrochloride during pregnancy and lactation has not been established; therefore, if it is to be given to pregnant patients, nursing mothers, or women of childbearing potential, the possible benefits must be weighed against the possible hazards to mother and child. Animal reproductive studies have been inconclusive. **4.** USE IN CHILDREN: Norpramin (desipramine hydrochloride) is not recommended for use in children since safety and effectiveness in the pediatric age group have not been established. **5.** The patient should be cautioned that this drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. **6.** In patients who may use alcohol excessively, it should be borne in mind that the potentiation may increase the danger inherent in any suicide attempt or overdosage.

PRECAUTIONS: 1. It is important that this drug be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with this class of drug. Ordinary prudence requires that children not have access to this drug or to potent drugs of any kind; if possible this drug should be dispensed in containers with child-resistant safety closures. Storage of this drug in the home must be supervised responsibly. **2.** If serious adverse effects occur, dosage should be reduced or treatment should be altered. **3.** Norpramin (desipramine hydrochloride) therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates. **4.** The drug may cause exacerbation of psychosis in schizophrenic patients. **5.** Close supervision and careful adjustment of dosage are required when this drug is given concomitantly with anticholinergic or sympathomimetic drugs. **6.** Patients should be warned that while taking this drug their response to alcoholic beverages may be exaggerated. **7.** Clinical experience in the concurrent administration of ECT and antidepressant drugs is limited. Thus, if such treatment is essential, the possibility of increased risk relative to benefits should be considered. **8.** The sedative effects of Norpramin and benzodiazepines (*e.g.*, chlordiazepoxide or diazepam) are additive. Both the sedative and anticholinergic effects of the major tranquilizers are additive to those of Norpramin. **9.** This drug should be discontinued as soon as possible prior to elective surgery because of the possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients taking desipramine hydrochloride. **10.** Both elevation and lowering of blood sugar levels have been reported. **11.** Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathologic neutrophil depression.

ADVERSE REACTIONS: Note: Included in the following listing are a few adverse reactions that have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when Norpramin (desipramine hydrochloride) is given.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurologic: numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus.

Anticholinergic: dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis, increased intraocular pressure; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs.

Hematologic: bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue.

Endocrine: gynecomastia in the male, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels.

Other: jaundice (simulating obstructive), altered liver function; weight gain or loss; perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

DOSAGE AND ADMINISTRATION: Not recommended for use in children. Lower dosages are recommended for elderly patients and adolescents. Lower dosages are also recommended for outpatients compared to hospitalized patients, who are closely supervised. Dosage should be initiated at a low level and increased according to clinical response and any evidence of intolerance. Following remission, maintenance medication may be required for a period of time and should be at the lowest dose that will maintain remission.

Usual Adult Dose: The usual adult dose is 100 to 200 mg. per day. In more severely ill patients, dosage may be further increased gradually to 300 mg./day if necessary. Dosages above 300 mg./day are not recommended.

Dosage should be initiated at a lower level and increased according to tolerance and clinical response.

Treatment of patients requiring as much as 300 mg. should generally be initiated in hospitals, where regular visits by the physician, skilled nursing care, and frequent electrocardiograms (ECG's) are available.

The best available evidence of impending toxicity from very high doses of Norpramin is prolongation of the QRS or QT intervals on the ECG. Prolongation of the PR interval is also significant, but less closely correlated with plasma levels. Clinical symptoms of intolerance, especially drowsiness, dizziness, and postural hypotension, should also alert the physician to the need for reduction in dosage. Plasma desipramine measurement would constitute the optimal guide to dosage monitoring.

Initial therapy may be administered in divided doses or a single daily dose.

Maintenance therapy may be given on a once-daily schedule for patient convenience and compliance.

Adolescent and Geriatric Dose: The usual adolescent and geriatric dose is 25 to 100 mg. daily.

Dosage should be initiated at a lower level and increased according to tolerance and clinical response to a usual maximum of 100 mg. daily. In more severely ill patients, dosage may be further increased to 150 mg./day. Doses above 150 mg./day are not recommended for these age groups.

Initial therapy may be administered in divided doses or a single daily dose.

Maintenance therapy may be given on a once-daily schedule for patient convenience and compliance.

OVERDOSAGE: See prescribing information for a discussion of symptoms and treatment of overdose.

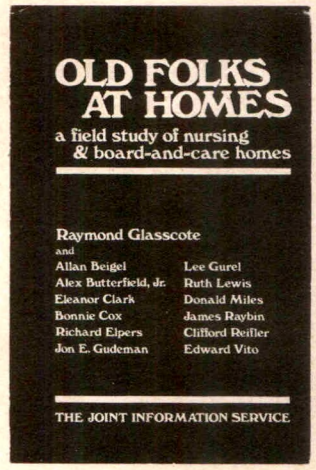
The Joint Information Service of the American Psychiatric Association and the Mental Health Association releases Two New Volumes That

Focus on the Elderly



This carefully documented book reports a field study of ten programs, four in America and six in England and Scandinavia, which serve as practical demonstrations of creative mental health services for the elderly. They include:

- a novel "Neighborhood Family" providing vigorous support to elderly residents of several trailer parks
- a high school for the elderly which sends its students abroad for study trips
- a "Human Development Project" that focuses on responding to the psychological needs of the elderly
- a carefully coordinated system of "respite hospitalization," which promotes the health of the elderly while allowing maximum use of hospital beds and family resources
- a "Lucy Booth," patterned after the Peanuts comic strip, which provides easy access to many kinds of services
- and many other innovative, successful approaches.

Each program is subjected to intensive scrutiny. The resulting document becomes a handbook, and, as well, a forum through which some of the world's most experienced practitioners of "the psychiatry of old age" present their views.

Dr. Wilma Donohue, director of the International Center for Social Gerontology, characterizes this volume as "a masterful job of putting everything in relief . . . the guidelines for action are right here."

190 pages. Casebound. Price $8.50.

Concerned about the very bad reputation that nursing homes have received from many quarters in recent years, the Joint Information Service set up a field study to visit a systematically chosen sample of nursing homes, and board-and-care homes as well, to see to what extent the care of and the quality of life for the patients differed from the geriatrics units of state hospitals. Altogether, sixty nursing homes and 31 board-and-care homes in ten locales were visited, in each case by the senior author accompanied by two mental health professionals.

The teams were surpised to learn that care and quality of life in many of the nursing and board-and-care homes they visited were better—sometimes dramatically better—than that in the mental health facilities and often at lower cost.

This unique publication provides an overview of all facilities visited plus vignettes of approximately half. Federal and state rules and regulations are also expertly synthesized into brief and readable style.

148 pages. Casebound. Price $6.50

The Prolixin® (Fluphenazine) system of schizophrenia management—

spanning virtually every clinical situation

There is scarcely a patient-type presenting with schizophrenia that cannot be successfully managed with one of the numerous forms of Prolixin (Fluphenazine).

For the newly admitted, agitated patient, a first choice would be short-acting Prolixin Injection (Fluphenazine Hydrochloride Injection USP).

For long-term management of more "dependable" patients, you have the titration flexibility of four potencies of Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP).

For patients who "cheek" or otherwise resist tablet medication, you can utilize pleasant tasting, orange-flavored Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP).

For long-term maintenance of less compliant patients, you can employ unique, long-acting Prolixin Decanoate (Fluphenazine Decanoate Injection) and achieve effective neuroleptization for up to four weeks and longer with a single injection.

See next page for brief summaries.

PROLIXIN® (Fluphenazine Hydrochloride)
TABLETS/ELIXIR/INJECTION

Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP) provide 1, 2.5, 5, or 10 mg fluphenazine hydrochloride per tablet. Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP) provides 0.5 mg fluphenazine hydrochloride per ml (2.5 mg per 5 ml teaspoonful) with 14% alcohol by volume. Prolixin Injection (Fluphenazine Hydrochloride Injection USP) provides 2.5 mg fluphenazine hydrochloride per ml; it contains 0.1% methylparaben and 0.01% propylparaben as preservatives.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to fluphenazine hydrochloride and other antipsychotic drugs is not known.

Periodic checking of hepatic and renal functions and blood picture should be done. Monitor renal function of patients on long-term therapy; if BUN becomes abnormal, discontinue fluphenazine. "Silent pneumonias" are possible.

Abrupt Withdrawal: In general, phenothiazines do not produce psychic dependence. However, gastritis, nausea and vomiting, dizziness, and tremulousness have been reported following abrupt cessation of high dose therapy; reports suggest that these symptoms can be reduced if concomitant antiparkinsonian agents are continued for several weeks after the phenothiazine is withdrawn.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. Most often these symptoms are reversible, but they may be persistent. They include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, hyperreflexia. The incidence and severity of such reactions will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of an anti-parkinsonian drug such as benztropine mesylate and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may need to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines.

For full prescribing information, consult package inserts.

HOW SUPPLIED: *Tablets*—5 mg in bottles of 50 and 500; 2.5 mg and 5 mg in bottles of 50 and 500 and in Unimatic® single-dose cartons of 100; 10 mg in bottles of 50 and 500. *Elixir*—in bottles of 473 ml (1 pint) and in 60 ml dropper-assembly bottles with dropper calibrated at 0.5 ml (0.25 mg), 1 ml (0.5 mg), 1.5 ml (0.75 mg), and 2 ml (1 mg). *Injection*—in multiple-dose vials of 10 ml.

PROLIXIN DECANOATE®
Fluphenazine Decanoate Injection

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg fluphenazine decanoate per ml in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage; patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Physicians should be alert to the possibility of severe adverse reactions may occur which require immediate medical attention. Potentiation effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician experienced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal function and blood picture should be done. Renal function of patients on long-term therapy should be monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneumonias" are possible.

There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to fluphenazine decanoate and other antipsychotic drugs is not known.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. Most often these symptoms are reversible, but they may be persistent. They include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, hyperreflexia. Muscle rigidity sometimes accompanied by hyperthermia has been reported following use of fluphenazine decanoate. One can expect a higher incidence of such reactions with fluphenazine decanoate than with less potent piperazine derivatives or straight-chain phenothiazines. The incidence and severity will depend more on individual patient sensitivity, dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of an antiparkinsonian drug such as benztropine mesylate and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

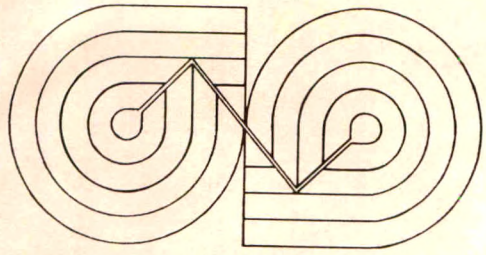
Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.



Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines. Local tissue reactions occur only rarely with injections of fluphenazine decanoate.

For full prescribing information, consult package insert.

HOW SUPPLIED: 1 ml Unimatic® single-dose preassembled syringes and cartridge units and 5 ml vials.

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

Brief Summary of Prescribing Information

ADAPIN® (doxepin HCl) Capsules

Indications—Relief of symptoms of anxiety and depression.

Contraindications—Glaucoma, tendency toward urinary retention, or hypersensitivity to doxepin.

Warnings—Adapin has not been evaluated for safety in pregnancy. No evidence of harm to the animal fetus has been shown in reproductive studies. There are no data concerning secretion in human milk, nor on effect in nursing infants.

Usage in children under 12 years of age is not recommended. MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug, as serious side-effects and death have been reported with the concomitant use of certain drugs and MAO inhibitors.

In patients who may use alcohol excessively potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions—Drowsiness may occur and patients should be cautioned against driving a motor vehicle or operating hazardous machinery. Since suicide is an inherent risk in depressed patients they should be closely supervised while receiving treatment. Although Adapin has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind.

Adverse Reactions—Dry mouth, blurred vision and constipation have been reported. Drowsiness has also been observed.

Adverse effects occurring infrequently include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as sweating, tachycardia and hypotension. Weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash and pruritus may also occur.

Dosage and Administration—In mild to moderate anxiety and/or depression: 25 mg t.i.d. Increase or decrease the dosage according to individual response. Daily dosage, up to 150 mg may be taken at bedtime without loss of effectiveness. Usual optimum daily dosage is 75 mg to 150 mg per day not to exceed 300 mg per day.

Antianxiety effect usually precedes the antidepressant effect by two or three weeks.

How Supplied—Each capsule contains doxepin, as the hydrochloride: **10 mg, 25 mg, 50 mg, and 100 mg** capsules in bottles of 100 and 1000.

For complete prescribing information please see package insert or PDR.

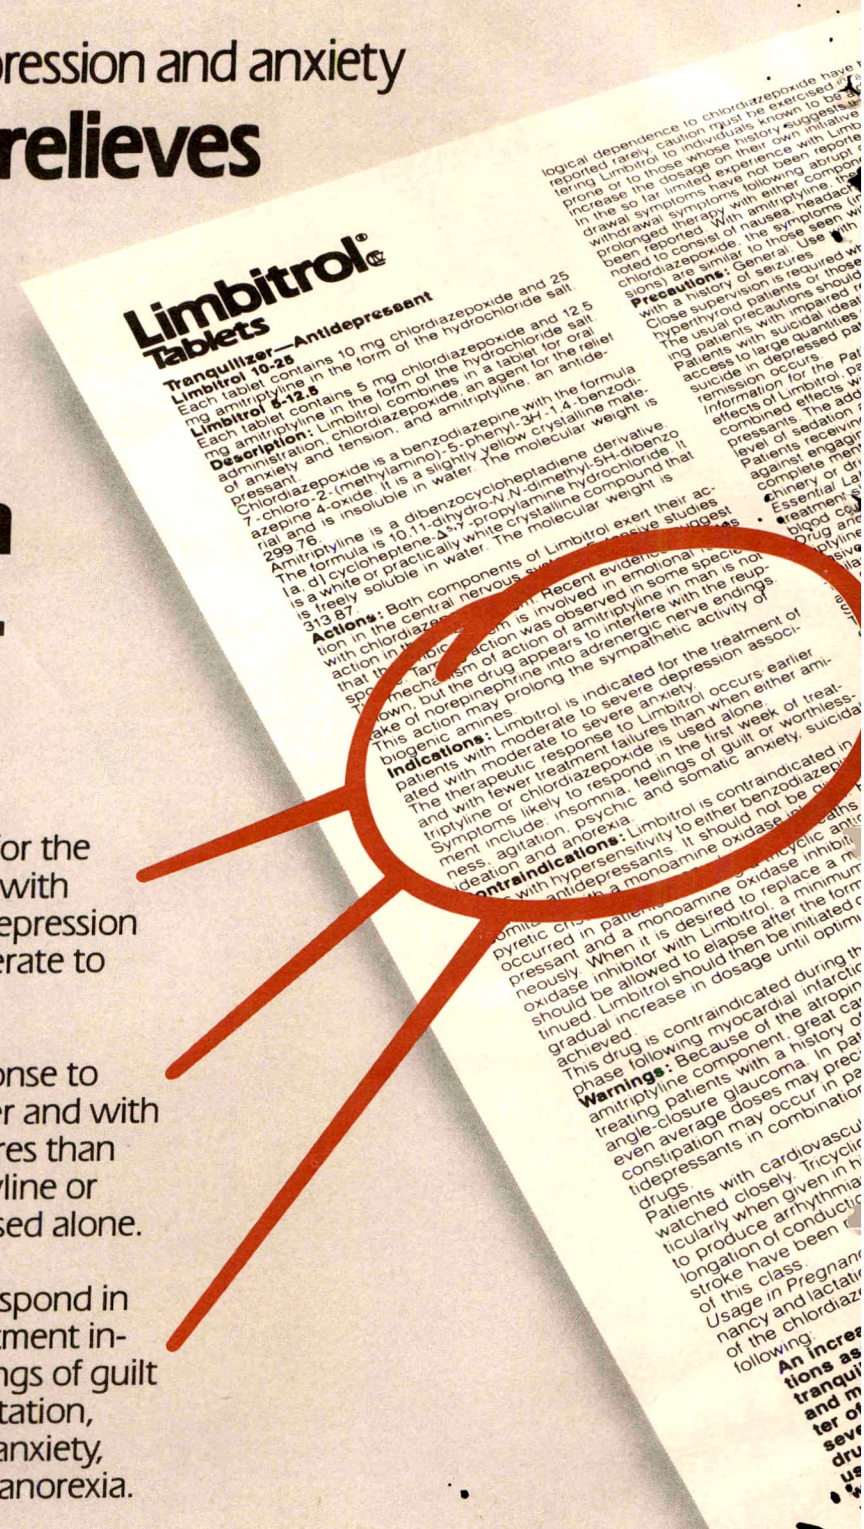
in anxiety/depression...

a good awakening from a good night's sleep

Most depressed patients experience some form of sleep disturbance. Adapin® helps relieve the accompanying anxiety, and restores a more normal sleep pattern right from the start of therapy.

☐ **convenient, flexible therapy**
The usual optimal dose is 75 to 150 mg daily. The entire dose may be given at night without loss of therapeutic effect. Adapin is available as 10 mg, 25 mg, 50 mg, and 100 mg capsules.

Adapin®
(doxepin HCl)
useful adjunctive therapy in your psychiatric practice



When they see life in shades of blue... help them see life in all its colors

In moderate depression and anxiety

Only Limbitrol relieves this range of symptoms this rapidly.

And without a phenothiazine.

Limbitrol®
Tablets

Tranquilizer—Antidepressant

Limbitrol 10-25
Each tablet contains 10 mg chlordiazepoxide and 25 mg amitriptyline in the form of the hydrochloride salt.

Limbitrol 5-12.5
Each tablet contains 5 mg chlordiazepoxide and 12.5 mg amitriptyline in the form of the hydrochloride salt.

Description: Limbitrol combines in a tablet for oral administration, chlordiazepoxide, an agent for the relief of anxiety and tension, and amitriptyline, an antidepressant.

Chlordiazepoxide is a benzodiazepine with the formula 7-chloro-2-(methylamino)-5-phenyl-3H-1,4-benzodiazepine 4-oxide. It is a slightly yellow crystalline material and is insoluble in water. The molecular weight is 299.76.

Amitriptyline is a dibenzocycloheptadiene derivative. The formula is 10,11-dihydro-N,N-dimethyl-5H-dibenzo [a, d] cycloheptene-Δ5,γ-propylamine hydrochloride. It is a white or practically white crystalline compound that is freely soluble in water. The molecular weight is 313.87.

Actions: Both components of Limbitrol exert their action in the central nervous system. Recent evidence suggests that the mechanism of action was observed in emotional states. This action may prolong the sympathetic activity of biogenic amines.

Indications: Limbitrol is indicated for the treatment of patients with moderate to severe depression associated with moderate to severe anxiety.

The therapeutic response to Limbitrol occurs earlier and with fewer treatment failures than when either amitriptyline or chlordiazepoxide is used alone.

Symptoms likely to respond in the first week of treatment include: insomnia, feelings of guilt or worthlessness, agitation, psychic and somatic anxiety, suicidal ideation and anorexia.

Contraindications: Limbitrol is contraindicated in patients with hypersensitivity to either benzodiazepines or tricyclic antidepressants. It should not be given in the presence of a monoamine oxidase inhibitor.

Pyretic crises, reactions resembling acute schizophrenic episodes, and convulsions have occurred in patients receiving amitriptyline alone or in combination with other drugs, including tricyclic antidepressant and a monoamine oxidase inhibitor. When it is desired to replace a monoamine oxidase inhibitor with Limbitrol, a minimum of 14 days should be allowed to elapse after the former is discontinued. Limbitrol should then be initiated at a low dosage and gradual increase in dosage until optimum response is achieved.

This drug is contraindicated during the acute recovery phase following myocardial infarction. **Warnings:** Because of the atropine-like effects of amitriptyline component, great caution should be used in treating patients with a history of urinary retention, angle-closure glaucoma. In patients receiving even average doses may occur in paralytic ileus. Constipation may occur in patients receiving tricyclic antidepressants in combination with drugs.

Patients with cardiovascular disease should be watched closely. Tricyclic antidepressants particularly when given in high doses, have been known to produce arrhythmias, sinus tachycardia, prolongation of conduction time, myocardial infarction, and stroke have been reported with the use of this class.

Usage in Pregnancy and lactation: Safe use of the chlordiazepoxide during pregnancy has not been established. Therefore, the following:

An increased incidence of congenital malformations associated with the use of minor tranquilizers and meprobamate during pregnancy has been reported in several studies. Barbiturates, chlordiazepoxide, and meprobamate have been shown to be teratogenic in animals. Limbitrol should not be used during pregnancy, especially during the first trimester of pregnancy, unless in the opinion of the physician the potential benefits outweigh the possible hazards.

Limbitrol is indicated for the treatment of patients with moderate to severe depression associated with moderate to severe anxiety.

The therapeutic response to Limbitrol occurs earlier and with fewer treatment failures than when either amitriptyline or chlordiazepoxide is used alone.

Symptoms likely to respond in the first week of treatment include: insomnia, feelings of guilt or worthlessness, agitation, psychic and somatic anxiety, suicidal ideation and anorexia.

Limbitrol.
Dual therapy with greater specificity...without classical phenothiazine drawbacks.

osage and recommendations for treatment are based on clinical experience with its components. Primary concern should be with the dangers associated with amitriptyline overdosage. Deaths by deliberate or accidental overdosage have occurred with this class of drugs.

All patients suspected of having an overdosage of Limbitrol should be admitted to a hospital as soon as possible.

Manifestations: High doses may cause drowsiness, temporary confusion, disturbed concentration or transient visual hallucinations. Overdosage may cause hypothermia, tachycardia and conduction disturbances (evidence of impaired conduction such as bundle branch block), congestive heart failure, dilated pupils, convulsions, severe hypotension, stupor and coma. Other symptoms may be agitation, hyperpyrexia or any of those muscle rigidity, vomiting, hyperactive reflexes, listed under Adverse Reactions.

Treatment: Empty the stomach as quickly as possible by emesis or lavage. In the comatose patient a cuff endotracheal tube should be placed in position prior to either of these measures. The stomach also should be considered. If charcoal into the stomach and nursing care may be required. It the patient is stuporous but responds to stimuli, only close observation and nursing care may be required. It essential to maintain an adequate airway and fluid intake. Body temperature should be watched closely and appropriate measures taken should deviations occur.

The intramuscular or slow intravenous administration of 1 to 3 mg in adults (or 0.5 mg in children) of physostigmine salicylate (Antilirium®) has been reported to reverse the manifestations of amitriptyline overdosage. Because of its relatively short half-life, additional doses may be needed at intervals of 30 minutes to 2 hours. Convulsions may be treated by the use of barbiturates. Cardiac anesthetic rather than the use of an inhalation or other antiarrhythmic agents should be considered if monitoring is advisable, and the cautious use of cardiac serious cardiovascular abnormalities occur. Serum potassium levels should be monitored and kept within normal limits by the use of appropriate I.V. fluids. Standard measures including oxygen, I.V. fluids, plasma expanders and corticosteroids may be used to control circulatory shock.

Dialysis is unlikely to be of value, as it has not proven useful in overdosages of either amitriptyline or chlordiazepoxide. Since many suicidal attempts involve multiple drugs including barbiturates, the possibility of dialysis being beneficial for removal of other drugs should not be overlooked.

Treatment should be continued for at least 48 hours, along with cardiac monitoring in patients who do not respond to therapy promptly. Since relapses are frequent, patients should be hospitalized until their conditions remain stable without physostigmine for at least 24 hours.

Since overdosage is often deliberate, patients may attempt suicide by other means during the recovery phase.

1. Granacher RP, Baldessarini RJ: Physostigmine. Its use in acute anticholinergic syndrome with antidepressant and antiparkinson drugs. Arch Gen Psychiatry 32:375-380, Mar 1975.
2. Burks JS, Walker JE, Rumack BH, Ott JE: Tricyclic antidepressant poisoning. Reversal of coma, choreoathetosis, and myoclonus by physostigmine. JAMA 230:1405-1407, Dec 9, 1974.
3. Snyder BD, Blonde L, McWhirter WR: Reversal of amitriptyline intoxication by physostigmine. JAMA 230:1433-1434, Dec 9, 1974.

Dosage and Administration: Optimum dosage varies with the severity of the symptoms and the response of the individual patient. When a satisfactory response is obtained, dosage should be reduced to the smallest amount needed to maintain the remission. The larger portion of the total daily dose may be taken at bedtime. In some patients, a single dose at bedtime may be sufficient. In general, lower dosages are recommended for elderly patients.

Limbitrol 10-25 is recommended in an initial dosage of three or four tablets daily in divided doses; this may be increased to six tablets daily as required. Some patients respond to smaller doses and can be maintained on two tablets daily.

Limbitrol 5-12.5 in an initial dosage of three or four tablets daily in divided doses may be satisfactory in patients who do not tolerate higher doses.

How Supplied: White, film-coated tablets, each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) and blue, film-coated tablets, each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles of 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 50.

THIS PRODUCT INFORMATION ISSUED OCTOBER 1978.

Limbitrol®

Tablets 10-25 each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt)

Tablets 5-12.5 each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)

Please see summary of product information on last page of this advertisement.

LIMBITROL® TABLETS Tranquilizer—Antidepressant

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.

Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants. Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.

Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.)

***Usage in Pregnancy:* Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage; withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).

Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated: sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12.

In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.

Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.

This list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs:

Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.

Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.

Anticholinergic: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urinary tract.

Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.

Hematologic: Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.

Endocrine: Testicular swelling and gynecomastia in the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female and elevation and lowering of blood sugar levels.

Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaundice, alopecia, parotid swelling.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. I.V. administration of 1 to 3 mg physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestation and treatment.

Dosage: Individualize according to symptom severity and patient response. Reduce to smallest effective dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bedtime. Single *h.s.* dose may suffice for some patients. Lower dosages are recommended for the elderly.

Limbitrol 10-25, initial dosage of three to four tablets daily in divided doses, increased up to six tablets or decreased to two tablets daily as required. Limbitrol 5-12.5, initial dosage of three to four tablets daily in divided doses, for patients who do not tolerate higher doses.

Supplied: Limbitrol 10-25 tablets each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) and Limbitrol 5-12.5 tablets each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles of 100 and 500; Tel-E-Dose* packages of 100; Prescription Paks of 50.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, New Jersey 07110

How to initiate and maintain therapy

Select dosage strength appropriate for each patient

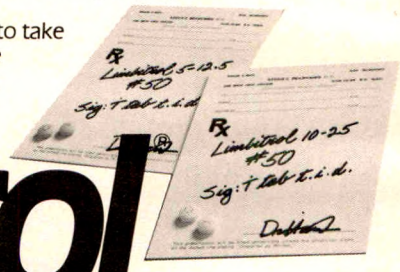
☐ Limbitrol 10-25 is recommended for most patients

☐ Limbitrol 5-12.5 may be indicated for those who do not tolerate higher doses and for elderly patients

Specify daily dosage based on symptom severity

☐ An initial dosage of three tablets is recommended.

☐ Dosage may be increased to six tablets or decreased to two tablets daily as necessary.



☐ Once a satisfactory response is obtained, evaluate response and, if necessary, reduce dosage to smallest amount needed.

Utilize dosage options to best accommodate individual patient needs

☐ T.I.D. or Q.I.D., familiar regimens most suited for patients who tolerate medication without undue drowsiness

☐ Two tablets one hour before bedtime and one tablet midday may minimize daytime drowsiness and help relieve a common target symptom—insomnia

☐ Entire dosage h.s. to take maximum advantage of the sedative effect

Limbitrol

Tablets 10-25 each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt)

Tablets 5-12.5 each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)

How to make each patient an informed patient

1. Discuss with patients the probability that they will experience drowsiness, especially during the first week.

2. Reassure your patients that drowsiness is one indication that the medication is working and that it may help alleviate their insomnia.

3. Encourage patients to report if drowsiness becomes troublesome so that, if necessary, dosage schedule can be adjusted or the symptom treated.

4. Caution patients about the combined effects with alcohol or other CNS depressants. Let them know that the additive effects may produce a harmful level of sedation and CNS depression.

5. Caution patients about activities requiring complete mental alertness, such as operating machinery or driving a car.

6. Warn pregnant patients and patients of childbearing age that the safety of Limbitrol in pregnancy has not yet been established.

Please see complete product disclosure for other pertinent information.

Limbitrol should not be used under the following circumstances:

1. Hypersensitivity to benzodiazepines or tricyclic antidepressants.
2. Should not be given with an MAO inhibitor. To replace an MAO inhibitor with Limbitrol, discontinue MAO inhibitor for a minimum of 14 days before cautiously initiating Limbitrol therapy.
3. During the acute recovery phase following myocardial infarction.

A50

a valuable link to the resources of the American Psychiatric Association

for institutions and agencies concerned with the care of the mentally disabled

Enrollment in the Hospital & Community Psychiatry Service brings multiple copies of *Hospital & Community Psychiatry* into member agencies every month, keeping staff up to date on developments and issues in the mental health field, offering new ideas and fresh perspectives, and serving as a useful resource in staff development and training programs.

Hospital & Community Psychiatry is just one of the benefits of membership in the H&CP Service. Others include a film library containing more than a hundred films specially chosen for their usefulness in staff development and community education programs; supplementary mailings of important books, reports, articles, or other material of special interest to administrators or clinicians; reduced registration fees at the annual fall Institute on Hospital & Community Psychiatry; and, on request, information and consultation from the professional staff of the American Psychiatric Association. The H&CP Service also sponsors the annual Achievement Awards competition, which gives special recognition to outstanding programs for the mentally ill and mentally retarded.

Please send me information about membership in the Hospital & Community Psychiatry Service.

The therapeutic window helps you see the difference between Pamelor® (nortriptyline HCl) and other antidepressants.

The Pamelor Therapeutic Window: a well-defined range of therapeutic blood levels.

All tricyclics have a range of steady-state plasma levels that produce maximal antidepressant effects and minimal toxic effects.[1] When this range is well-defined it is called the "therapeutic window." To date, conclusive evidence for a therapeutic window has been obtained for only one tricyclic—nortriptyline.[2]

Highly predictable determination of optimal dosage

The more accurately the limits of the therapeutic window are defined, the more predictably individual dosage requirements for a tricyclic agent can be determined.[2] That's why an initial starting dose of 75 mg Pamelor daily can achieve optimal plasma levels for 70% of depressed patients.[3] A single dosage adjustment to 100 mg Pamelor daily will achieve therapeutic blood levels for most patients who have not responded to 75 mg.

Minimal titration

With other tricyclic agents, the therapeutic dose is usually determined by increasing the daily dose from 25 mg upward to 300 mg. This time-consuming and often random process of titration is virtually eliminated with Pamelor. Because the initial dose is usually a therapeutic dose, you can spend less time on dosage adjustment and more time on psychotherapy.

Minimal significant side effects

Pamelor therapy is well tolerated. Daytime drowsiness is rarely a problem. As with all antidepressants, however, patients should be cautioned against driving or operating hazardous machinery. Anticholinergic side effects are also minimal, although some patients may experience dry mouth.

Pamelor therapy is clinically effective

Improvement of symptoms of depression can often begin to be seen in some patients within a week. These include relief of depressed mood, sleep disturbances, and fatigue. Global improvement is usually observed by the second week. Maximum improvement with Pamelor, as with other antidepressants, may require longer therapy particularly in severe depressive illnesses.

Pamelor®
(nortriptyline HCl) NF
25mg. Capsules

Helps make the therapeutic dosage easy to determine.

For brief summary please see last page of this advertisement.

SANDOZ
PHARMACEUTICALS
East Hanover, N.J. 07936

Pamelor® (nortriptyline HCl) NF 25mg. Capsules

Helps make the therapeutic dosage easy to determine for depressed patients.

- ☐ highly predictable determination of optimal dosage
- ☐ minimal titration
- ☐ minimal significant side effects
- ☐ Pamelor therapy is clinically effective

Indications: For relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Hypersensitivity. Should not be given concomitantly with MAO inhibitors or within 2 weeks of the use of this drug since hyperpyretic crises, severe convulsions, and fatalities have occurred when similar tricyclic antidepressants were used in such combinations. Cross-sensitivity with other dibenzazepines is a possibility. Contraindicated during acute recovery period after myocardial infarction.

Warnings: Use with caution in patients with cardiovascular disease because of tendency to produce sinus tachycardia and prolong conduction time. Myocardial infarction, arrhythmia, and strokes have occurred. May block antihypertensive action of guanethidine and similar agents. Because of anticholinergic activity, use cautiously in patients with glaucoma or a history of urinary retention. Patients with a history of seizures should be followed closely because the drug is known to lower the convulsive threshold. Great care is required for hyperthyroid patients and those taking thyroid medication because of possible development of cardiac arrhythmia. Caution patients about possibility of impaired mental and/or physical ability to operate a motor vehicle or dangerous machinery. Response to alcoholic beverages may be exaggerated and may lead to suicidal attempts. Safe use during pregnancy, lactation, and women of childbearing potential has not been established and the drug should not be given unless clinical situation warrants potential risk. Not recommended for use in children.

Precautions: Psychotic symptoms may be exacerbated in schizophrenic patients. Increased anxiety and agitation may occur in overactive or agitated patients. Manic-depressive patients may experience shift to manic phase. Hostility may be aroused. Concomitant administration of reserpine may produce a "stimulating" effect. Watch for possible epileptiform seizures during treatment. Use cautiously with anticholinergic or sympathomimetic drugs. Concurrent electroconvulsive therapy may increase hazards associated with nortriptyline HCl. When possible, discontinue drug several days prior to surgery. Potentially suicidal patients require supervision and protective measures during therapy. Prescriptions should be limited to the least possible quantity. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: The pharmacologic similarities among the tricyclic antidepressant drugs require that each of the following reactions be considered when nortriptyline is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia, panic, nightmares; hypomania; exacerbation of psychosis.

Neurologic: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alteration in EEG patterns; tinnitus.

Anticholinergic: Dry mouth and rarely, associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue), drug fever, cross-sensitivity with other tricyclic drugs.

Hematologic: Bone-marrow depression, including agranulocytosis; eosinophilia; purpura; thrombocytopenia.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black-tongue.

Endocrine: Gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency, nocturia; drowsiness, dizziness, weakness, fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though these are not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

Dosage and Administration: *Usual adult dose*—25 mg. three or four times daily; dosage should begin at a low level and increase as required. As an alternate regimen, the total daily dosage may be given once-a-day. *Elderly and Adolescent*—30 to 50 mg. per day, in divided doses, or the total dosage may be given once-a-day. Doses above 100 mg. per day and use in children are not recommended. If a patient develops minor side effects, the dosage should be reduced. The drug should be discontinued promptly if adverse effects of a serious nature or allergic manifestations occur.

How Supplied: Capsules 10 mg. and 25 mg.; solution 10 mg./5 cc.

For more detailed information see full prescribing information.

SANDOZ East Hanover, N.J. 07936

The American Psychiatric Association announces publication of two volumes reporting the Conference on Education of Psychiatrists

held at Lake of the Ozarks, Missouri, June 9-15, 1975. Organized by the A.P.A. in cooperation with the American Academy of Child Psychiatry, the American Association of Chairmen of Departments of Psychiatry, and the American Association of Directors of Psychiatric Residency Training.

1. PSYCHIATRIC EDUCATION: PROLOGUE TO THE 1980's, Library Bound, 544 pages, $15.00.

This is a substantive, highly readable, report of the Conference, written by Anne H. Rosenfeld with an Editorial Board comprising: Ewald W. Busse, M.D., Chairperson of the Conference, Walter E. Barton, M.D., Bernard Holland, M.D., Donna Norris, M.D., Melvin Sabshin, M.D., Jeanne Spurlock, M.D., and Robert L. Robinson, M.A. (Staff Consultant).

The volume contains ten chapters covering the topical structure of the Conference: Goals and Values; Competence, Evaluation, and Quality Control; The Resident; Faculty; Educational Methods: Means in the Service of Ends; The Program Environment; Research; The Economics of Residency Training; Psychiatry in Its Social Context; and Retrospect and Prospect. It also contains nine appendices describing the organization of the Conference and its participants, together with selected model programs and related informational materials of value.

2. THE WORKING PAPERS OF THE 1975 CONFERENCE ON EDUCATION OF PSYCHIATRISTS Paper bound, 432 pages, $12.50.

Sixty two leading psychiatric educators served on seven preparatory commissions, one for each of seven topic areas, and prepared advance working papers as a basis for Conference deliberations. The topics and Commission Chairpersons were: Social Issues and Needs (James N. Sussex, M.D.); Goals and Objectives (Morton F. Reiser, M.D.); The Resident (David R. Hawkins, M.D.); Content, Methodology, Faculty and Environment (Milton Greenblatt, M.D.); Research (Daniel X. Freedman, M.D.); Economics (Herzl Spiro, M.D.); Evaluation and Quality Control (Eric Pfeiffer, M.D.). The Chairpersons, together with the Conference Chairperson, served as the Editorial Board for this volume.

Papers commenting on the reports of the commissions, published here for the first time, were presented at the Conference by Melvin Sabshin, M.D., Eugene B. Brody, M.D., Jeanne Spurlock, M.D., Jack R. Ewalt, M.D., Robert J. Stoller, M.D., James R. Comer, M.D., and Bernard Holland, M.D.

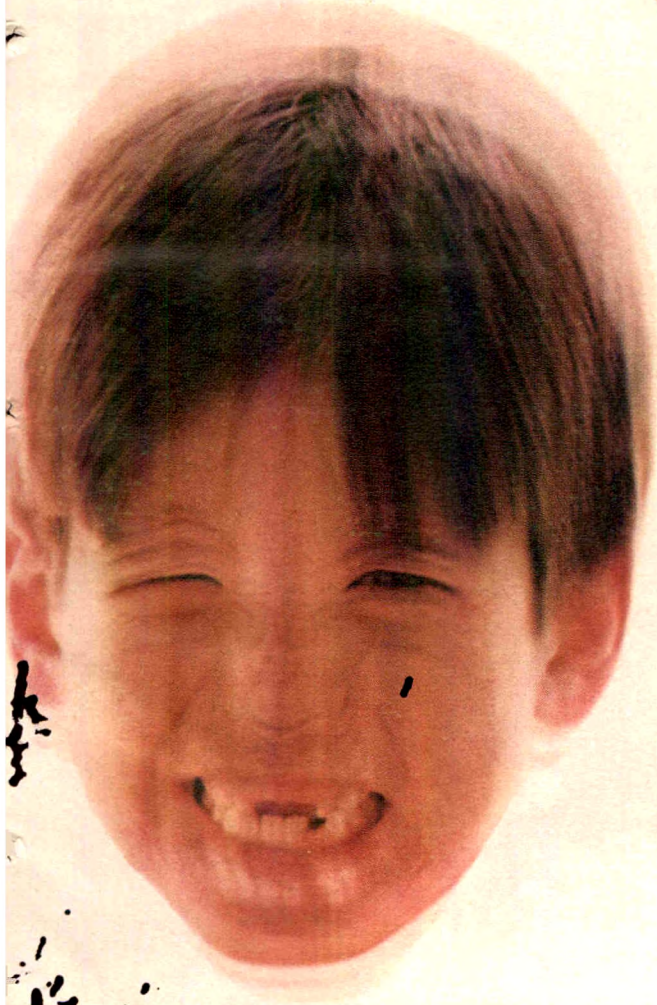
THE MANY FACES

Help for the apathetic/ withdrawn geriatric*

For the aged person suffering from withdrawn or apathetic senile behavior, Ritalin can often help relieve bothersome symptoms. In one double-blind study[1] of withdrawn, apathetic geriatric patients, Ritalin elicited notable improvement in competence, interest and retardation. While no side effects were reported in this study, blood pressure and pulse variations were noted in both groups but were not considered of exceptional magnitude.

Help for narcoleptic patients

The narcoleptic patient can fall asleep anytime...anyplace... and the consequences can be grave, or at the least, embarrassing. Although there is no known cure for narcolepsy, Ritalin acts promptly to counteract sleepiness and is the medication most frequently used by cited investigators.[2,3] Occasional problems of tolerance may be managed by complete withdrawal of Ritalin during vacation or holidays, then reinstating the drug at lower dosage.[3]

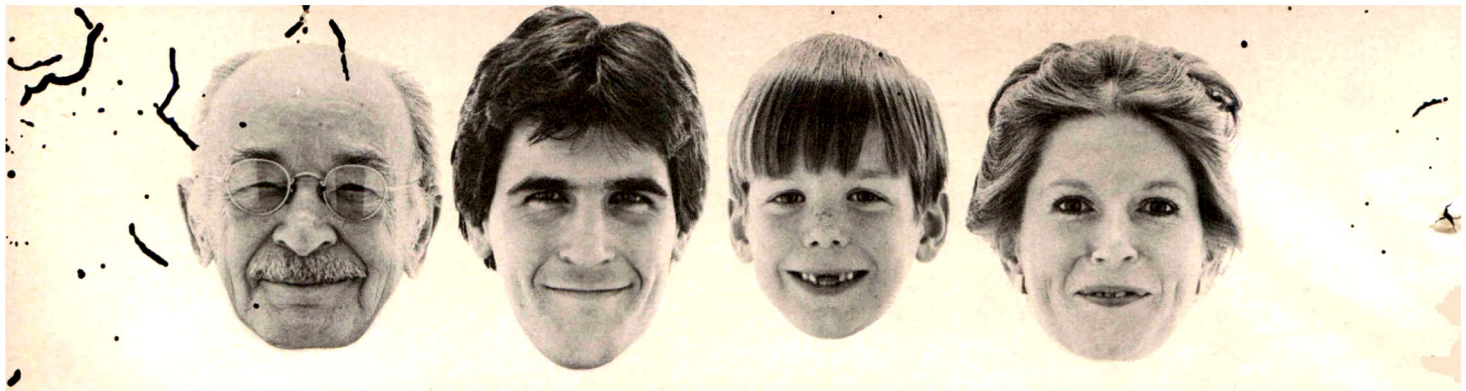


*Ritalin has been evaluated as possibly effective in these indications.

OF RITALIN® CII
(methylphenidate)

Help for patients with mild depression*

As Ritalin acts promptly to relieve symptoms of mild depression, mood and outlook usually improve, and the patient can cope again. Generally, one prescription is sufficient. Ritalin is contraindicated in severe depression.



Help for the MBD child

For the child with Minimal Brain Dysfunction (MBD), adjunctive Ritalin is often highly effective when medication is needed to help reduce symptoms such as distractibility,[4] disorganized behavior,[4] and hyperactivity.[4] MBD children responding to Ritalin usually exhibit better classroom performance and improved interpersonal relationships. Moreover, as MBD symptoms are curbed, the affected child often responds more positively to nonpharmacologic modalities.[5] Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is temporarily or permanently discontinued.

Please turn page for prescribing information.

SO MUCH HELP FOR SO MANY PATIENTS

Ritalin® hydrochloride Ⓒ
(methylphenidate hydrochloride USP)

TABLETS

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
Effective: Minimal Brain Dysfunction in Children—as adjunctive therapy to other remedial measures (psychological, educational, social)
Special Diagnostic Considerations
Specific etiology of Minimal Brain Dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.
Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate to severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.
Drug treatment is not indicated for all children with MBD. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.
Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.
Effective: Narcolepsy
"Possibly" effective: Mild Depression; Apathetic or Withdrawn Senile Behavior
Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS
Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.
Sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.
Ritalin should not be used for severe depression of either exogenous or endogenous origin.
Ritalin should not be used for the prevention or treatment of normal fatigue states.

There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.
Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.
Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions
Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.
Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy
Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence
Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.
Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS
Patients with an element of agitation may react adversely; discontinue therapy if necessary.
Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS
Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported.
Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia, a few instances of scalp hair loss.
In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION
Adults
Administer orally in divided doses 2 or 3 times daily, preferably 30 to 45 minutes before meals. Dosage will depend upon indication and individual response.
Average dosage is 20 to 30 mg daily. Some patients may require 40 to 60 mg daily. In others, 10 to 15 mg daily will be adequate. Patients who are unable to sleep if medication is taken late in the day should take the last dose before 6 p.m.
Children with Minimal Brain Dysfunction
(6 years and over)
Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.
If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.
Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is either temporarily or permanently discontinued.
Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED
Tablets, 20 mg (peach, scored); bottles of 100 and 1000.
Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.
Tablets, 5 mg (pale yellow); bottles of 100, 500 and 1000.

PSYCHIATRIST MEDICAL DIRECTOR

Saskatchewan Health, Psychiatric Services Branch invites applications for the position of Medical Director, Saskatchewan Hospital North Battleford.

Saskatchewan, Canada is internationally known for pioneering the community care approach while maintaining a tradition of high quality service. This particular position affords you a unique career opportunity to be involved in a well functioning, comprehensive mental health service for a population of 95,000.

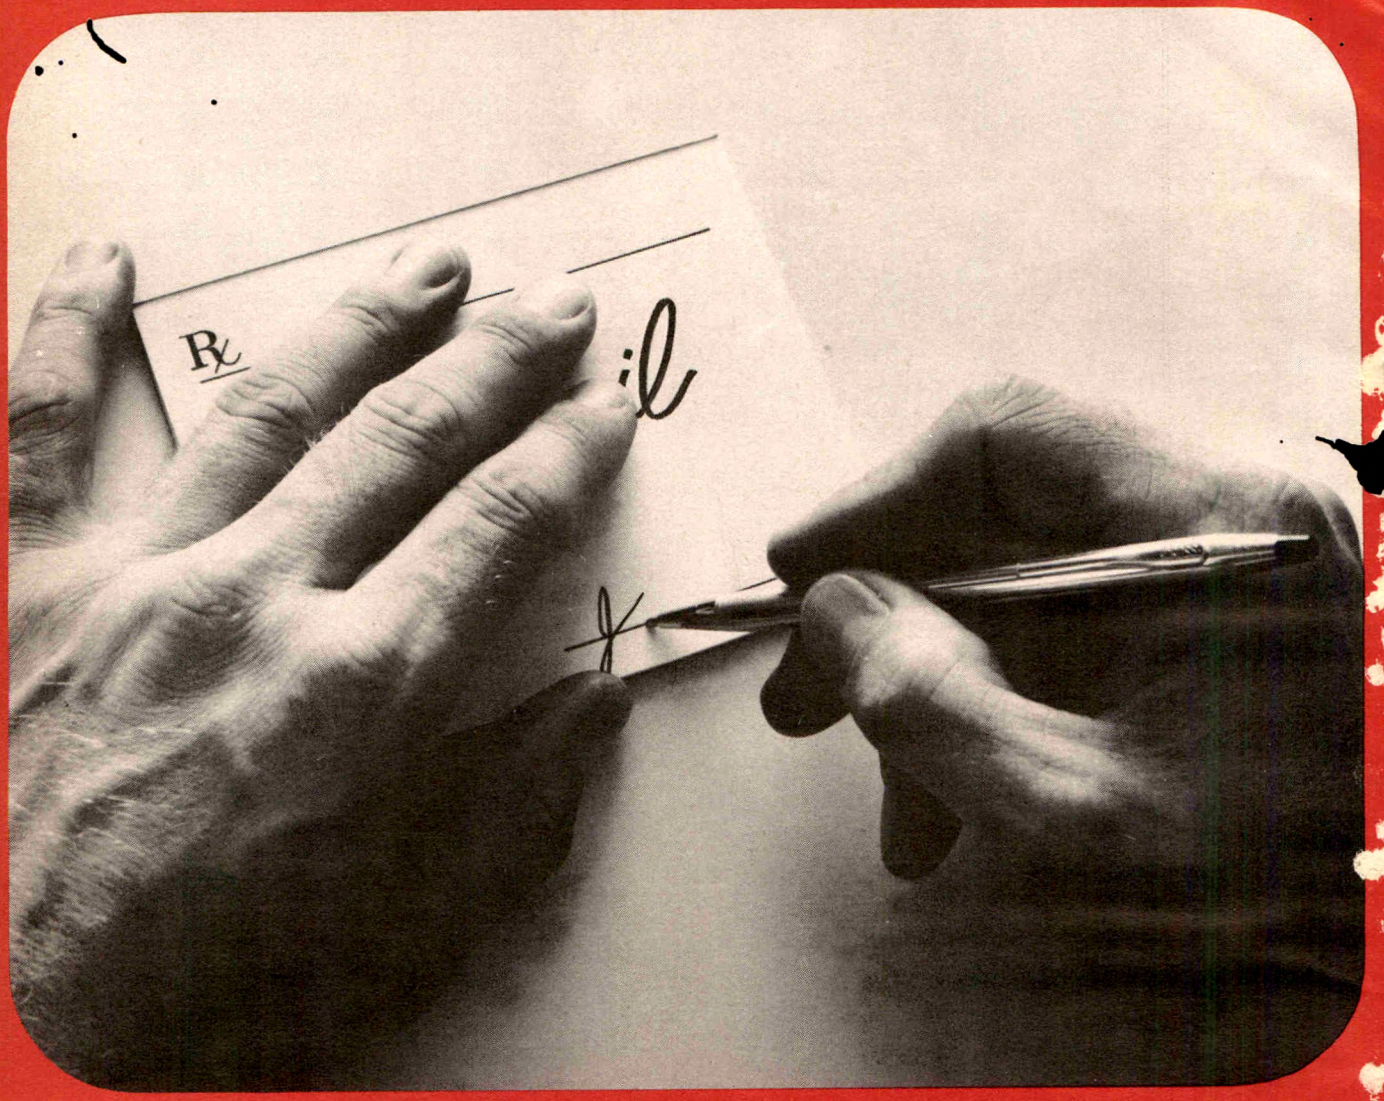
The delivery of this community based program is accomplished through interdisciplinary teams drawn from professional groups composed of psychologists, psychiatric social workers, community nurses, therapists, nurses and support staff.

As the Medical Director you will, within the guidelines established by the Branch and the Executive Director, have considerable freedom and influence with responsibility for effective and efficient clinical service. You will direct and control the admission, treatment and discharge procedures and have complete responsibility for assignments and evaluation of a medical staff of nine.

Applicants must have postgraduate psychiatric training and be eligible for full license in Saskatchewan. Graduates of approved medical schools in the United Kingdom, Ireland, South Africa, Australia, New Zealand, Canada and the United States may be eligible for license.

The appointment to this position will be on a contract basis.

BASIC SALARY: up to $61,068 per annum and commensurate with qualifications and experience



Relocation Assistance is available.

North Battleford is situated on the scenic North Saskatchewan River and minutes away from some of Saskatchewan's most scenic lakes, fishing areas, and parkland. Our pollution-free environment offers skiing, curling, skating, swimming, camping, sailing and good schools.

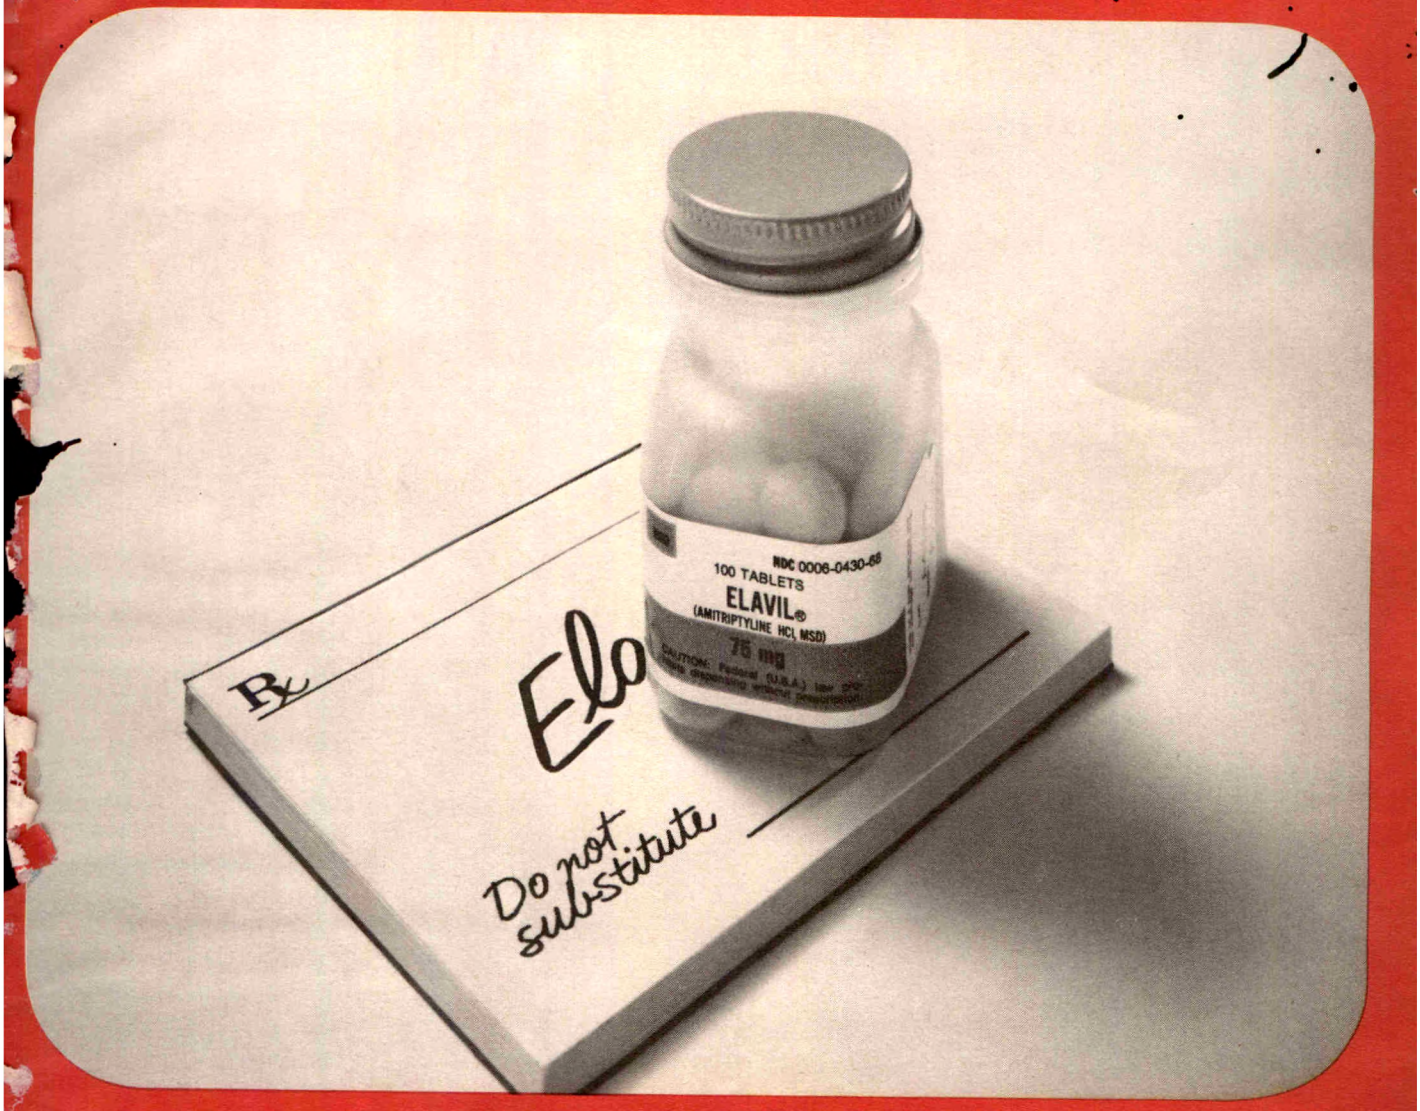
Inquiries and/or resumes should be directed to:

Dr. H. G. Lafave,
Executive Director
Psychiatric Services Branch
3475 Albert Street
Regina, Saskatchewan
S4S 6X6

There is no substitute

yours...

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.



Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.

When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappro

for experience—

or ours.

priate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

Psychiatrists

Staff positions are available on the teaching ward of a large state hospital we're affiliated with. Positions involve direct patient care, staff supervision, and treatment program planning...and offer the possibility of faculty appointments to do research and to teach medical students, residents, and doctoral students in Psychology.

Competitive salary and excellent benefits provided; Pennsylvania State license and Board certification or eligibility required.

Forensic Psychiatrist

Position involves innovative approaches to treatment and evaluation of court ward patients. Possibility of faculty appointment for teaching and research provided jointly by state hospital and Hahnemann.

Competitive salary and excellent benefits provided; Pennsylvania State license and Board certification or eligibility required.

To apply for either of these positions, please address your resume to: **Israel Zwerling, MD, PhD, Professor and Chairman, Department of Mental Health Sciences, HAHNEMANN MEDICAL COLLEGE & HOSPITAL, 230 N. Broad St., Philadelphia, Pa. 19102.** *An equal opportunity employer M/F.*

Hahnemann Medical College & Hospital

ST. JOHN OF GOD BROTHERS' CHILD & FAMILY GUIDANCE SERVICES

Applications are invited for the position of

CONSULTANT CHILD PSYCHIATRIST

IRELAND

The St. John of God Service in Ireland provides a comprehensive Child Psychiatric Service for a catchment area of over 500,000, including South Dublin and Wicklow.

The following professional qualifications and experience are required for this appointment, which carries a salary of £12,360. per annum:

1. Possession of the MD* degree in psychiatry of a recognized university, or the MRCPI in psychiatry, or membership of the Royal College of Psychiatrists, or the Diploma in Psychological Medicine awarded before February 1972, or a professional qualification at least equivalent to one of these.

   *Other than a primary degree.

2. At least seven years satisfactory experience in the practice of the medical profession, including not less than five years satisfactory experience in psychiatry, of which not less than three years was in child psychiatry.

Applications should be addressed to:

The Reverend Brother Director,
St. John of God Brothers' Child & Family Guidance Services,
59 Orwell Road, Rathgar, Dublin 6, Ireland.
Telephone: (01) 977596.

Everybody knows somebody who's been helped.

The United Way is reaching out. It goes into every neighborhood. To every age group. Across every income level.
To help. In a thousand ways.
A neighbor. A relative. Maybe someone down the street who's out of work. Or sick. Or in trouble.
Chances are the United Way helps someone you know.
Maybe someday it'll be helping you.

Thanks to you it works...

Prescribing Information for

Lidone™ (molindone hydrochloride)

DESCRIPTION — LIDONE (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

LIDONE is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4(5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

ACTIONS — LIDONE (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditional response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, LIDONE antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, LIDONE exerts its effect on the ascending reticular activating system.

Human metabolic studies show LIDONE (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24 to 36 hours. There are 36 recognized metabolites with less than 2 to 3% unmetabolized LIDONE being excreted in urine and feces.

INDICATIONS — LIDONE (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS — LIDONE (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy: Studies in pregnant patients have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats Oral Dose —
20 mg/kg/day — 10 days, no adverse effect
40 mg/kg/day — 10 days, no adverse effect

Pregnant Mice Oral Dose —
20 mg/kg/day — 10 days, slight increase resorptions
40 mg/kg/day — 10 days, slight increase resorptions

Pregnant Rabbits Oral Dose —
5 mg/kg/day — 12 days, no adverse effect
10 mg/kg/day — 12 days, no adverse effect
20 mg/kg/day — 12 days, no adverse effect

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of LIDONE (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of LIDONE (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

PRECAUTIONS — Some patients receiving LIDONE (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until response to the drug has been established.

...ased activity has been noted in patients ...g LIDONE. Caution should be exercised ...creased activity may be harmful.

...E does not lower the seizure threshold in ...ntal animals to the degree noted with ...ating antipsychotic drugs. However, con... ...eizures have been reported in a few ...

ADVERSE REACTIONS

CNS Effects — The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological Extrapyramidal Reactions — Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia — Motor restlessness may occur early.

Parkinson Syndrome — Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome — Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System — Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological — There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with LIDONE may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects — Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Lactation associated with LIDONE therapy has not been reported. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with LIDONE.

Cardiovascular — Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological — Lens opacities and pigmentary retinopathy have not been reported where patients have received LIDONE (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with LIDONE.

Skin — Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with LIDONE usage alone.

LIDONE (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when LIDONE is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia — Although rarely reported with LIDONE (molindone hydrochloride) symptoms were reversible upon discontinuation of therapy.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). There may be involuntary movements of extremities.

There is no known effective treatment of tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

DOSAGE AND ADMINISTRATION — Initial and maintenance doses of LIDONE (molindone hydrochloride) should be individualized.

Initial Dosage Schedule

The usual starting dosage is 50 to 75 mg/day.
- — Increase to 100 mg/day in three or four days
- — Based on severity of symptomatology, dosage may be titrated up or down depending on individual patient response.
- — An increase to 225 mg/day may be required in patients with severe symptomatology.
- — Some chronic, treatment-resistant patients may require up to 400 mg/day; (however, the long-term safety of 400 mg/day has not been established).

Elderly or debilitated patients should be started on lower dosage.

Maintenance Dosage Schedule

1. Mild — 5 mg to 15 mg three or four times a day
2. Moderate — 10 mg to 25 mg three or four times a day.
3. Severe — 225 mg/day may be required.

Dosage may be administered once a day.

DRUG INTERACTIONS — Potentiation of drugs administered concurrently with LIDONE (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when LIDONE is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE — Symptomatic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction of absorption of LIDONE (molindone hydrochloride) which is freely soluble in water.

Since the adsorption of LIDONE (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.

Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by LIDONE in animals, this blocking effect has not been determined in humans.

A significant increase in the rate of removal of unmetabolized LIDONE from the body by forced diuresis, peritoneal or renal dialysis would not be expected. (Only 2% of a single ingested dose of LIDONE is excreted unmetabolized in the urine. However, poor response of the patient may justify use of these procedures.

While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized LIDONE in feces is less than 1%. Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents (i.e. Artane*, Cogentin*, Akineton*).

HOW SUPPLIED — LIDONE (molindone hydrochloride) capsules are supplied in bottles of 10 in the following dosage strengths and colors:

5 mg (**NDC** 0074-5542-13) blue and cream
10 mg (**NDC** 0074-5543-13) red and cream
25 mg (**NDC** 0074-5544-13) brown and cream

TM — Trademark
*Benadryl — Trademark, Parke Davis and Co.
*Artane — Trademark, Lederle Laboratories
*Cogentin — Trademark, Merck Sharp & Dohme
*Akineton — Trademark, Knoll Pharmaceutical Co.

Treats schizophrenic target symptoms

with less likelihood of certain troublesome effects

5, 10, 25 mg capsules

Lidone™
(Molindone HCl)

See overleaf for prescribing information

Significant gains are reported in control of hallucinations, conceptual disorganization, hostility, unusual thought content, emotional withdrawal.

Yet no reports of persistent tardive dyskinesia, excessive weight gain, impotence, lens opacities, skin pigmentation; and only rare cases of significant hypotension. Other side effects are similar to comparable agents.
